A plain abdominal X-ray or barium enema shows a small rectum and colonic dilatation above the narrowed segment. Full-thickness biopsies are required to demonstrate nerve plexuses and confirm the absence of ganglion cells. Histochanelic acids for acetylcholinesterase are also used. Anorectal manometry demonstrates failure of the internal sphincter to relax with balloon distension. Treatment involves resection of the affected segment.

### Acquired megacolon

This may develop in childhood as a result of voluntary withholding of stool during toilet training and can present with faecal impaction and soiling. In such cases, it presents after the first year of life and is distinguished from Hirschsprung’s disease by the urge to defecate and the presence of stool in the rectum. It usually responds to osmotic laxatives.

In adults, acquired megacolon has several causes. It is seen in patients with depression or dementia, either as part of the condition or as a side-effect of antidepressant drugs. Prolonged misuse of stimulant laxatives may cause degeneration of the myenteric plexus, while interruption of sensory or motor innervation may be responsible in a number of neurological disorders. Patients taking large doses of opioid analgesics can develop a megacolon: so-called ‘narcotic bowel syndrome’. Systemic sclerosis and hypothyroidism are other recognised causes.

Most patients can be managed conservatively by treatment of the underlying cause, high-residue diets, laxatives and the judicious use of enemas. Prokinetics are helpful in a minority of patients. Opioid-induced constipation can be treated with the specific peripheral opioid receptor antagonists, such as naloxegol, methylnaltrexone and nalatedemine. Subtotal colectomy is a last resort for the most severely affected patients.

### Acute colonic pseudo-obstruction

Acute colonic pseudo-obstruction (Ogilvie syndrome) has many causes (Box 23.58) and is characterised by sudden onset of painless, massive enlargement of the proximal colon; there are no features of mechanical obstruction. Bowel sounds are normal or high-pitched, rather than absent. Left untreated, it may progress to perforation, peritonitis and death.

Abdominal X-rays show colonic dilatation with air extending to the rectum. Caecal diameter greater than 10 cm is associated with a high risk of perforation. CT with contrast demonstrates the absence of mechanical obstruction.

Management consists of treating the underlying disorder and correcting any biochemical abnormalities. The anticholinesterase neostigmine is effective in enhancing parasympathetic activity and gut motility. Decompression, with either a rectal tube or colonoscope, may be effective but needs to be repeated until the condition resolves. In severe cases, surgical or fluoroscopic defunctioning caecostomy is necessary.

### Haemorrhoids

Haemorrhoids (commonly known as piles) arise from congestion of the internal and/or external venous plexuses around the anal canal. They are extremely common in adults. The aetiology is unknown, although they are associated with constipation and straining, and may develop for the first time during pregnancy. First-degree piles bleed, while second-degree piles prolapse but retract spontaneously. Third-degree piles are those that require manual replacement after prolapsing. Bright red rectal bleeding occurs after defecation. Other symptoms include pain, pruritus ani and mucus discharge; thrombosis can occur in prolapsed piles, which can be very painful (Fig. 23.54). Treatment involves measures to prevent constipation and straining. Band ligation is effective for many, but a minority of patients require haemorroidectomy, which is usually curative. Haemorroidal artery ligation operation (HALO) procedures have been developed and may replace surgery. HALO involves using Doppler ultrasound to identify all the arteries feeding the haemorrhoids and subsequent ligation.

### Pruritus ani

This is common and can stem from many causes (Box 23.59), most of which result in contamination of the perianal skin with faecal contents.

Itching may be severe and results in an itch–scratch–itch cycle that exacerbates the problem. When no underlying cause is found, all local barrier ointments and creams must be stopped. Good personal hygiene is essential, with careful washing after defecation. The perineal area must be kept dry and clean. Bulk-forming laxatives may reduce faecal soiling.

### Solitary rectal ulcer syndrome

This is most common in young adults and occurs on the anterior rectal wall. It is thought to result from localised chronic trauma and/or ischaemia.

---

**Causes of acute colonic pseudo-obstruction**

- Trauma, burns
- Recent surgery
- Drugs (opiates, phenothiazines)
- Respiratory failure
- Electrolyte and acid–base disorders (e.g. hypokalaemia, hypomagnesaemia)
- Diabetes mellitus – autonomic dysfunction
- Uraemia

---

Fig. 23.54 Thrombosed prolapsed haemorrhoids.
associated with disordered puborectalis function and mucosal prolapse. The ulcer is seen at sigmoidoscopy and biopsies show a characteristic accumulation of collagen.

Symptoms include minor bleeding and mucus per rectum, tenesmus and perineal pain. Treatment is often difficult, but avoidance of straining at defecation is important and treatment of constipation may help. Marked mucosal prolapse is treated surgically.

### Anal fissure

In this common problem, traumatic or ischaemic damage to the anal mucosa results in a superficial mucosal tear, most commonly in the midline posteriorly. Spasm of the internal anal sphincter exacerbates the condition. Severe pain occurs on defecation and there may be minor bleeding, mucus discharge and pruritus. The skin may be indurated and an oedematous skin tag, or ‘sentinel pile’, adjacent to the fissure is common.

Avoidance of constipation with bulk-forming laxatives and increased fluid intake is important. Relaxation of the internal sphincter is normally mediated by nitric oxide and 0.2% glyceryl trinitrate, which donates nitric oxide and improves mucosal blood flow, is effective in 60%-80% of patients. Diltiazem cream (2%) can be used as an alternative. Resistant cases may respond to injection of botulinum toxin into the internal anal sphincter to induce relaxation. Manual dilatation under anaesthesia leads to long-term incontinence and should not be considered. The majority of cases can be treated without surgery, but where these measures fail, healing can be achieved surgically by lateral internal anal sphincterotomy or advancement anoplasty.

### Anorectal abscesses and fistulae

Perianal abscesses develop between the internal and external anal sphincters and may point at the perianal skin. Ischiorectal abscesses occur lateral to the sphincters in the ischiorectal fossa. They usually result from infection of anal glands by normal intestinal bacteria. Crohn's disease (see below) is sometimes responsible.

Patients complain of extreme perianal pain, fever and/or discharge of pus. Spontaneous rupture may lead to the development of fistulae. These may be superficial or track through the anal sphincters to reach the rectum. Abscesses are drained surgically and superficial fistulae are laid open with care to avoid sphincter damage.

### Faecal incontinence

The normal control of anal continence is described on page 788. Common causes of incontinence are listed in Box 23.60. High-risk patients include frail older people, women after childbirth and those with severe neurological/spinal disorders, learning disabilities or cognitive impairment.

Patients are often embarrassed to admit to incontinence and may complain only of ‘diarrhoea’. A careful history and examination, especially of the anorectum and perineum, may help to establish the underlying cause. Endoanal ultrasound is valuable for defining the integrity of the anal sphincters, while anorectal physiology and MR proctography are also useful investigations.

### Management

This is often very difficult. Underlying disorders should be treated and diarrhoea managed with loperamide, diphenoxylate or codeine phosphate. Attention must be paid to a proper diet and adequate fluid intake. Pelvic floor exercises, biofeedback and bowel retraining techniques help some patients, and those with confirmed anal sphincter defects may benefit from sphincter repair operations. Where sphincter repair is not appropriate, a trial of sacral nerve stimulation is undertaken with a view to insertion of a permanent stimulator but, if unsuccessful, creation of a neo-sphincter may be possible, by graciloplasty or by an artificial anal sphincter.

### Inflammatory bowel disease

Ulcerative colitis and Crohn's disease are chronic inflammatory bowel diseases that pursue a protracted relapsing and remitting course, usually extending over years. The diseases have many similarities and it is sometimes impossible to differentiate between them. One crucial distinction is that ulcerative colitis involves only the colonic mucosa, while Crohn's disease can involve any part of the gastrointestinal tract from mouth to anus. A summary of the main features of ulcerative colitis and Crohn's disease is provided in Box 23.61.

The incidence of inflammatory bowel disease (IBD) varies widely between populations. The highest incidence is in North America, Europe and Oceania. A rapid increase in incidence in the 21st century has been seen in newly industrialised countries in Asia, Africa and South America, with the adoption of an increasingly Westernised lifestyle.

Both diseases most commonly start in the second and third decades of life, with a second smaller incidence peak in the seventh decade. The number of people with IBD over the age of 65 years, however, is increasing, and it is becoming more common in younger children. Approximately 620,000 people are affected by IBD in the UK, with a prevalence of 0.5%-1%. Life expectancy in patients with IBD is similar to that of the general population. Although many patients require surgery and admission to hospital for other reasons, with substantial associated morbidity, the majority have an excellent work record and pursue a normal life.

### Pathophysiology

IBD has both environmental and genetic components, and evidence from genome-wide association studies suggests that genetic variants that predispose to Crohn's disease may have undergone positive selection by protecting against infectious diseases, including tuberculosis (Box 23.62). It is thought that IBD develops because these genetically susceptible individuals mount an abnormal inflammatory response to environmental triggers, such as intestinal bacteria. This leads to inflammation of the intestine with involvement of a wide array of innate and adaptive immune cell responses, with release of inflammatory mediators, including tumour necrosis factor alpha (TNF-α), interleukin (IL)-12 and IL-23, which cause tissue damage (Fig. 23.55). There appears to be an association between microbial dysbiosis and IBD. For example, there is a reduced diversity, primarily of Firmicutes and Bacteroides,
and a relative increase in Enterobacteriaceae. Functional changes in the bacteria are important and include a reduction of anti-inflammatory metabolites, such as butyrate and other short-chain fatty acids. While microbial dysbiosis has been recognised in IBD, a causal role has yet to be established. There is emerging evidence that the virome and mycobiotics (fungal species) may be important in the development of IBD. In both diseases, the intestinal wall is infiltrated with acute and chronic inflammatory cells, but there are important differences between the conditions in the distribution of lesions and in histological features (Fig. 23.56).

### 23.62 Factors associated with the development of inflammatory bowel disease

**Genetic**
- Both CD and UC are common in Ashkenazi Jews
- 10% have first-degree relative/one or more close relative with IBD
- High concordance in identical twins (40%–50% CD; 20%–25% UC)
- 163 susceptibility loci identified at genome-wide levels of significance; most confer susceptibility to both CD and UC; many are also susceptibility loci for other inflammatory conditions (especially ankylosing spondylitis and psoriasis)
- UC and CD are both associated with genetic variants at HLA locus, and with multiple genes involved with immune signalling (especially IL-23 and IL-10 pathways)
- CD is associated with genetic defects in innate immunity and autophagy (NOD2, ATG16L1 and IRGM genes)
- UC is associated with genetic defects in barrier function
- NOD2 is associated with ileal and stricture disease, and hence a need for resectional surgery
- HLA-DR*103 is associated with severe UC

**Environmental**
- UC is more common in non-smokers and ex-smokers
- CD is more common in smokers (relative risk = 3)
- CD is associated with a low-residue, high-refined-sugar diet
- Commensal gut microbes are altered (dysbiosis) in CD and UC
- Appendectomy protects against UC

**CD** = Crohn’s disease; **HLA** = human leucocyte antigen; **IBD** = inflammatory bowel disease; **IL** = interleukin; **UC** = ulcerative colitis

**Fig. 23.55 Pathogenesis of inflammatory bowel disease.** (1) Bacterial antigens are taken up by specialised M cells, pass between leaky epithelial cells or enter the lamina propria through ulcerated mucosa. (2) After processing, they are presented to type 1 T-helper cells by antigen-presenting cells (APCs) in the lamina propria. (3) T-cell activation and differentiation results in a Th1, Th cell-mediated cytokine response (4) with secretion of cytokines, including interferon gamma (IFN-γ). Further amplification of T cells perpetuates the inflammatory process with activation of non-immune cells and release of other important cytokines, including interleukin (IL)-12, IL-23, IL-1, IL-6 and tumour necrosis factor alpha (TNF-α). These pathways occur in all normal individuals exposed to an inflammatory insult and this is self-limiting in healthy subjects. In genetically predisposed persons, dysregulation of innate immunity may trigger inflammatory bowel disease.

**Ulcerative colitis**

Inflammation invariably involves the rectum (proctitis) and spreads proximally in a continuous manner to involve the entire colon in some cases (pancolitis). In long-standing pancolitis, the bowel can become...
shortened and post-inflammatory ‘pseudopolyps’ develop; these are normal or hypertrophied residual mucosa within areas of atrophy (Fig. 23.57). The inflammatory process is limited to the mucosa and spares the deeper layers of the bowel wall (Fig. 23.58). Both acute and chronic inflammatory cells infiltrate the lamina propria and the crypts (‘cryptitis’). Crypt abscesses are typical. Goblet cells lose their mucus and, in long-standing cases, glands become distorted. Dysplasia, characterised by heaping of cells within crypts, nuclear atypia and increased mitotic rate, may herald the development of colon cancer.

Crohn’s disease

The sites most commonly involved, in order of frequency, are the terminal ileum and right side of the colon, the small intestine, the colon alone, and the perianal region (Fig. 23.56). The entire wall of the bowel is oedematous and thickened, and there are deep ulcers that often appear as linear fissures; thus the mucosa between them is described as ‘cobblestone’. These may penetrate through the bowel wall to initiate abscesses or fistulae involving the bowel, bladder, uterus, vagina and skin of the perineum. The mesenteric lymph nodes are enlarged and the mesentry is thickened. Crohn’s disease has a patchy distribution and the inflammatory process is interrupted by islands of normal mucosa, resulting in ‘skip lesions’. On histological examination, the bowel wall is thickened with a chronic inflammatory infiltrate throughout all layers (Fig. 23.59).

**Clinical features**

**Ulcerative colitis**

The cardinal symptoms are rectal bleeding with passage of mucus and bloody diarrhoea. The presentation varies, depending on the site and severity of the disease (see Fig. 23.56), as well as the presence of extra-intestinal manifestations. The first attack is usually the most severe and is followed by relapses and remissions. Emotional stress, intercurrent infection, gastroenteritis, antibiotics or NSAID therapy may all provoke a relapse. Proctitis causes rectal bleeding and mucus discharge, accompanied by tenesmus. Some patients pass frequent, small-volume fluid stools, while others pass pellety stools due to constipation upstream of the inflamed rectum. Constitutional symptoms rarely occur. Left-sided and extensive colitis causes bloody diarrhoea with mucus, often with abdominal cramps. In severe cases, anorexia, malaise, weight loss and abdominal pain occur and the patient is toxic, with fever, tachycardia and signs of peritoneal inflammation (Box 23.63).

**Fig. 23.58** Histology of ulcerative colitis. There is surface ulceration and inflammation is confined to the mucosa with excess inflammatory cells in the lamina propria, loss of goblet cells and crypt abscesses (arrows). (SM = submucosa)
Crohn's disease

The major symptoms are abdominal pain, diarrhoea and weight loss. Ileal Crohn's disease (Figs. 23.60 and 23.61) may cause subacute or even acute intestinal obstruction. Patients can occasionally present with a perforated abscess. Abdominal pain is often associated with diarrhoea, which is usually watery and does not contain blood or mucus. Patients may lose weight because they avoid food, since eating provokes pain. Weight loss may also be due to malabsorption and some patients present with features of fat, protein or vitamin deficiencies. Crohn's colitis presents in an identical manner to ulcerative colitis, but rectal sparing and the presence of perianal disease are features that favour a diagnosis of Crohn's disease. Many patients present with symptoms of both small bowel and colonic disease. A few patients present with isolated perianal disease, vomiting from jejunal strictures or severe oral ulceration.

Physical examination often reveals evidence of weight loss, anaemia with glossitis and angular stomatitis. There is abdominal tenderness, most marked over the inflamed area. An abdominal mass may be palpable and is due to matted loops of thickened bowel or an intra-abdominal abscess. Perianal skin tags, fissures or fistulae are found in at least 50% of patients.

**Differential diagnosis**

The differential diagnosis is summarised in Box 23.64. The most important issue is to distinguish the first attack of acute colitis from infection. In general, diarrhoea lasting longer than 10 days in Western countries is unlikely to be the result of infection, whereas a history of foreign travel, antibiotic exposure (Clostridiodes difficile/pseudomembranous colitis) or homosexual contact increases the possibility of infection, which should be excluded by the appropriate investigations (see below). The

*The Truelove–Witts criteria for acute severe ulcerative colitis are ≥ 6 bloody stools/24hrs plus one or more of: anaemia, fever, tachycardia and high inflammatory markers.
diagnosis of Crohn’s disease is usually more straightforward and is made on the basis of imaging and clinical presentation, but in atypical cases biopsy or surgical resection is necessary to exclude other diseases (Box 23.65).

Complications
Life-threatening colonic inflammation
This can occur in both ulcerative colitis and Crohn’s colitis. In the most extreme cases, the colon dilates (toxic megacolon) and bacterial toxins pass freely across the diseased mucosa into the portal and then systemic circulation. This complication arises most commonly during the first attack of colitis and is recognised by the features described in Box 23.63. An abdominal X-ray should be taken daily because, when the transverse colon is dilated to more than 6 cm (Fig. 23.62), there is a high risk of colonic perforation, although this complication can also occur in the absence of toxic megacolon. Severe colonic inflammation with toxic dilatation is a surgical emergency and often requires colectomy.

Haemorrhage
Haemorrhage due to erosion of a major artery is rare, but can occur in both conditions. This is more common in Crohn’s disease, where deep ulceration erodes larger vessels.
staining with indigo carmine or methylene blue increase the chance of detecting dysplasia and this technique (termed pancolonic chromoendoscopy) has replaced colonoscopy with random biopsies taken every 10 cm in screening for malignancy. The procedure allows patients to be stratified into high-, medium- or low-risk groups to determine the interval between surveillance procedures. Family history of colon cancer is also an important factor to consider. If high-grade dysplasia is found, panproctocolectomy is usually recommended because of the high risk of colon cancer.

**Extra-intestinal complications**

Extra-intestinal complications are common in IBD and may dominate the clinical picture. Some of these occur during relapse of intestinal disease; others appear to be unrelated to intestinal disease activity (Fig. 23.63).

**Investigations**

Investigations are necessary to confirm the diagnosis, define disease distribution and activity, and identify complications. Full blood count may show anaemia resulting from bleeding or malabsorption of iron, folic acid or vitamin B12. Platelet count can also be high as a marker of chronic inflammation. Serum albumin concentration falls as a consequence of protein-losing enteropathy, inflammatory disease or poor nutrition. ESR and CRP are elevated in exacerbations and in response to abscess formation. Fecal calprotectin has a high sensitivity for detecting gastrointestinal inflammation and may be elevated, even when the CRP is normal. It is particularly useful for distinguishing inflammatory bowel disease from irritable bowel syndrome at diagnosis, and for subsequent monitoring of disease activity.

**Bacteriology**

At initial presentation, stool microscopy, culture and examination for *Clostridioides difficile* toxin or for ova and cysts, blood cultures and serological tests should be performed. These investigations should be repeated in established disease to exclude superimposed enteric infection in patients who present with exacerbations of IBD. During acute flares necessitating hospital admission, three separate stool samples should be sent for bacteriology to maximise sensitivity.

**Endoscopy**

Patients who present with diarrhoea plus raised inflammatory markers or alarm features, such as weight loss, rectal bleeding and anaemia, should undergo ileocolonoscopy. Flexible sigmoidoscopy is occasionally performed to make a diagnosis, especially during acute severe presentations when ileocolonoscopy may confer an unacceptable risk; ileocolonoscopy should still be performed at a later date, however, in order to evaluate disease extent. In ulcerative colitis, there is loss of vascular pattern, granularity, friability and contact bleeding, with or without ulceration (Fig. 23.64). In Crohn’s disease, patchy inflammation, with discrete, deep ulcers, strictures and perianal disease (fissures, fistulae and skin tags), is typically observed, often with rectal sparing. In established disease, coloroscopy may show active inflammation with pseudopolyps or a complicating carcinoma. Biopsies should be taken from each anatomical segment (terminal ileum, right colon, transverse colon, left colon and rectum) to confirm the diagnosis and define disease extent, and also to seek dysplasia in patients with long-standing colitis guided by pancolonic chromoendoscopy. In Crohn’s disease, wireless capsule
endoscopy has a greater sensitivity for detecting small bowel disease in comparison to radiological techniques and is useful when there is a high suspicion of Crohn’s despite normal imaging. Enteroscopy may be required to make a histological diagnosis of small bowel Crohn’s disease, when the inflamed segment is out of reach of standard endoscopes, or for a therapeutic indication, such as dilatation of strictures. In individuals with upper gastrointestinal symptoms, an upper gastrointestinal endoscopy may be useful. However, this is not routinely used in adults with suspected or proven Crohn’s disease.

Radiology
Where colonoscopy is incomplete, a CT colonogram is preferred. Small bowel imaging is essential to complete staging of Crohn’s disease. Traditional contrast imaging by barium follow-through demonstrates affected areas of the bowel as narrowed and ulcerated, often with multiple strictures (see Fig. 23.61). This has largely been replaced by MRI enterography, which does not involve exposure to radiation and is a sensitive way of detecting extra-intestinal manifestations and of assessing pelvic and perineal involvement. These studies use an orally administered small bowel-distending agent and intravenous contrast to provide transmural imaging that can usefully distinguish between predominantly inflammatory strictures (that should respond to anti-inflammatory medical strategies) and fibrotic strictures (that require a mechanical solution, such as surgical resection, stricturoplasty or endoscopic balloon dilatation). A plain abdominal X-ray is essential in the management of patients who present with severe active disease. Dilatation of the colon (see Fig. 23.62), mucosal oedema (thumb-printing) or evidence of perforation may be found. Patients with proctitis may have features of proximal faecal loading. In small bowel Crohn’s disease, there may be evidence of intestinal obstruction or displacement of bowel loops by a mass. Ultrasound is a very powerful tool to detect small bowel inflammation and stricture formation, but it is operator-dependent. The role of CT is limited to screening for complications, such as perforation or abscess formation, in the acutely unwell.

Management
Medical therapy plays an important role in the management of IBD. However, optimal management depends on establishing a multidisciplinary team-based approach involving physicians, surgeons, radiologists, nurse specialists and dietitians. Both ulcerative colitis and Crohn’s disease are life-long conditions and have important psychosocial implications; specialist nurses, counsellors and patient support groups have key roles in education, reassurance and coping. The key aims of medical therapy are to:
- treat acute attacks (induce remission)
- prevent relapses (maintain remission)
- prevent bowel damage
- detect dysplasia and prevent carcinoma
- select appropriate patients for surgery.

Medical therapy
Several medical treatment options exist in the management for IBD. Whilst traditional management for IBD has been through the use of non-biologic treatments, there has been a rapid expansion in the use of biologics, with common treatments described below.

Non-biologic therapies
Non-biologics used in IBD are summarised in Box 23.66.

Aminosalicylates (5-ASA)
5-ASAs are more commonly used in ulcerative colitis than in Crohn’s disease. 5-ASAs are thought to have multiple anti-inflammatory effects, including inhibition of mediators of lipoxigenase and cyclooxygenase, modulating cytokine release from the mucosa. Several types are available, with different means of delivery to the colon; pH-dependent (Asacol, Salofalk), time-dependent (Pentasa) or bacterial breakdown by colonic bacteria from a carrier molecule (sulfasalazine, balsalazine). While sulfasalazine was the first 5-ASA to be used in IBD, side-effects are common, such as headache, nausea, diarrhoea and blood dyscrasias. Other 5-ASAs are better tolerated. 5-ASAs can be administered orally or topically (suppositories or enema). Patients commencing a 5-ASA should have their urea and electrolytes checked at baseline, after 2–3 months and then annually, as nephrotoxicity can occur rarely (1 in 4000 patient years).

Glucocorticoids
Glucocorticoids such as prednisolone, hydrocortisone, budesonide and beclomethasone can be used to induce clinical remission in both ulcerative colitis and Crohn’s disease, but have no role in preventing relapse. They can be administered orally, topically (suppositories or enema) or intravenously and have powerful anti-inflammatory effects. When administered, it is important to have high vigilance for complications, such as
osteoporosis, diabetes and weight gain. Simultaneous calcium and vitamin D supplementation should be given for bone protection. Budesonide is a potent glucocorticoid, which is efficiently cleared from circulation by the liver, thereby minimising adrenocortical suppression and side-effects. It is commonly considered for active ileitis and ileocolitis.

**Thiopurines**

Thiopurines used in IBD are azathioprine and mercaptourine. They are immunomodulators that induce T-cell apoptosis. Azathioprine and mercaptopurine are administered orally and metabolised to thioguanine nucleotides (TGNs). Thiopurine methyltransferase (TPMT) metabolises thiopurine metabolites away from TGNs and affects drug levels. Leucopenia can occur in 3%, particularly in inherited TPMT deficiency. TPMT levels are checked prior to starting treatment and thiopurines are avoided if deficient/very low due to risk of toxicity. Thiopurines take around 6 weeks after starting treatment to be effective. Around 20% of patients will have complications leading to drug withdrawal. Complications include influenza-like syndrome with myalgia, nausea and vomiting. Genetic variation of NUDT15 has been described in association with myelosuppression and testing is performed if available. Other adverse effects include hepatotoxicity and pancreatitis. Patients are counselled on the increase lymphoma (approximately 2–3-fold) and non-melanoma skin cancer (life-long sun protection advised) risk. Caution is taken in prescribing thiopurines in patients presenting over the age of 60 years due to risk of malignancy.

**Methotrexate**

Methotrexate can be used for maintenance therapy in Crohn’s disease, with no role in ulcerative colitis. It is commonly used in individuals who have failed to respond with thiopurines. It is a folic acid antagonist, which inhibits dihydrofolate reductase, preventing DNA synthesis. The bioavailability of oral methotrexate is variable when compared to parenteral administration, with the subcutaneous injection being generally preferred to intramuscular due to ease of administration. Nausea, stomatitis, diarrhoea, hepatotoxicity and pneumonitis can occur with methotrexate. Folic acid should be given concurrently to reduce gastrointestinal and liver toxicity. Women of child-bearing potential must use a robust contraceptive method and should be counselled to plan pregnancy with a 6-month methotrexate-free period prior to conception as it is teratogenic.

**Ciclosporin**

Ciclosporin is a calcineurin inhibitor, inhibiting in particular the transcription of interleukin-2. It is used in ulcerative colitis that has responded poorly to glucocorticoids and has no role in Crohn’s disease. Major side-effects include nephrotoxicity, infections and neurotoxicity (including fits). Minor complications include tremor, paraesthesiae, abnormal liver function tests and hirsutism. Acutely, ciclosporin is usually administered intravenously, with responders to treatment converted to oral administration, which is continued for several months as a bridging therapy. Thiopurine maintenance therapy is commonly given as maintenance subsequently, as ciclosporin has no benefit as maintenance therapy.

**Antibiotics**

Antibiotics are useful in perianal Crohn’s disease and pouchitis. There is little evidence comparing different antibiotics for acute pouchitis, although ciprofloxacin is better tolerated with fewer adverse effects than metronidazole. The major concern is peripheral neuropathy with long-term metronidazole, with tendon inflammation and damage potentially occurring with ciprofloxacin. Combination antibiotics may be needed for chronic pouchitis. Antibiotics tend to be used in combination with thiopurines and anti-TNF therapy in perianal disease.

**Biologic agents**

Several classes of biologic agents are used in the management of IBD, with their indication shown in Box 23.67 and site of action shown in Fig. 23.65. The majority of biologics are administered either intravenously or subcutaneously, with the exception of tofacitinib, which is administered orally.

**Anti-TNF antibodies**

These include infliximab, adalimumab, golimumab and certolizumab. They are monoclonal antibodies that bind to TNF-α, preventing pro-inflammatory and pathological cytokine release by TNF-α. Acute (anaphylactic) and delayed (serum sickness) infusion reactions can occur after multiple infusions. Anti-drug antibody titres and drug levels can be also measured to assess efficacy. Anti-TNF antibodies are contraindicated in infection; reactivation of latent tuberculosis and moderate to severe cardiac failure can occur. In view of this, assessment for latent tuberculosis and hepatitis B and C prior to commencement is required. There is a possible increased risk of malignancy and, rarely, neurological adverse events. Treatment should occur until treatment failure, or should be reassessed after 12 months.

**Anti-α4β7 integrin**

 Vedolizumab is a monoclonal antibody that blocks α4β7 integrin expressed on leukocytes and inhibits leukocyte interaction with a gut-specific receptor on endothelium, reducing leukocyte migration into gut mucosa. It is a gut-selective biologic used in both ulcerative colitis and Crohn’s disease. Side-effects include nasopharyngitis, arthralgia and headache. Treatment is discontinued if there is no improvement after 14 weeks. Treatment should occur until treatment failure, or should be reassessed after 12 months.

**Janus kinase inhibitor**

Tofacitinib is a Janus kinase inhibitor that selectively inhibits the Janus-associated tyrosine kinases JAK1 and JAK3, blocking pro-inflammatory cytokine signalling via the STAT pathway. It has the advantage of oral administration in comparison to other biologics being used in ulcerative colitis. High doses should be avoided in patients at risk of pulmonary embolism and it is contraindicated in pregnancy. Herpes zoster has been noted to occur more often on active treatment; zoster vaccination is therefore recommended in those over age of 70 years or high-risk individuals (recurrent shingles) over 50 years.

**Anti-p40 antibodies**

Ustekinumab is a monoclonal antibody that binds to p-40 subunit of both IL-12 and IL-23 to prevent T-cell activation; it is used in both ulcerative colitis and Crohn’s disease. Side-effects include nasopharyngitis, headache and arthralgia. Treatment should occur until treatment failure or should be reassessed after 12 months.

**The therapeutic drug monitoring**

Up to one-third of patients do not respond to biologic therapy (primary non-response), with up to a half discontinuing biologic therapy after initial response due to secondary loss of response or adverse effects. This can be due to pharmacokinetic or pharmacodynamic issues of the drug. Favourable outcomes have been associated with good drug concentrations, with low levels leading to immunogenicity and drug failure. Therapeutic drug monitoring can be performed with biologic therapy, ensuring patients have adequate drug levels, pre-emptively preventing flares due to low drug levels. Combination treatment of biologics with thiopurines or methotrexate can be used to prevent and reduce anti-drug antibodies. Drug monitoring can also be performed with thiopurines, with thiopurine metabolites measured to tailor therapy.

**Ulcerative colitis**

**Active ulcerative colitis**

Patients with active ulcerative colitis are initially treated with topical or oral 5-aminosalicylate (5-ASA) therapy. Patients with left-sided or extensive ulcerative colitis should continue oral 5-ASA in the long term to prevent relapse and minimise the risk of dysplasia. Individuals with an incomplete response to 5-ASA treatment may require treatment with systemic glucocorticoids, immunomodulator or biologic therapy. Glucocorticoids

**Glucocorticoids**

Severe ulcerative colitis

Patients who fail to respond to maximal oral therapy and those who present with acute severe colitis (meeting the Truelove–Witts criteria; see Box 23.63) are best managed in hospital and should be monitored jointly by a physician and surgeon:

- **clinically**: for the presence of abdominal pain, temperature, pulse rate, stool blood and frequency

Fig. 23.66 Medical management of active ulcerative colitis.
23.68 Medical management of fulminant ulcerative colitis

- Admit to hospital for intensive therapy and monitoring
- Give IV fluids and correct electrolyte imbalance
- Consider transfusion if haemoglobin is < 100 g/L (< 10 g/dL)
- Give IV methylprednisolone (60 mg daily) or hydrocortisone (100 mg four times daily)
- Give antibiotics until enteric infection is excluded
- Arrange nutritional support
- Give subcutaneous low-molecular-weight heparin for prophylaxis of venous thromboembolism
- Avoid opiates and antidiarrhoeal agents
- Consider infliximab (5 mg/kg) or ciclosporin (2 mg/kg) in stable patients not responding to 3–5 days of glucocorticoids

(IV = intravenous)

- by laboratory testing: haemoglobin, white cell count, albumin, electrolytes, ESR and CRP, stool culture, including Clostridoides difficile toxin assay
- radiologically: for colonic dilatation on plain abdominal X-rays.

All patients should be given supportive treatment with intravenous fluids to correct dehydration and enteral nutritional support should be provided for malnourished patients (Box 23.68). Intravenous glucocorticoids (methylprednisolone 60 mg every 24 hours or hydrocortisone 100 mg four times daily) should be given by infusion or bolus injection. Patients should receive prophylactic low-molecular weight heparin, as the risk of venous thromboembolism is 2–3-fold higher compared to inpatients without IBD. Topical and oral aminosalicylates have no role to play in the acute severe attack. Response to therapy is judged over the first 3 days. Patients who do not respond promptly to glucocorticoids should be considered for medical rescue therapy with ciclosporin (2 mg/kg daily by intravenous infusion followed by 5 mg/kg daily, then orally after 7 days) or infliximab (5 mg/kg), which can avoid the need for urgent colectomy in approximately 60% of cases.

Patients who develop colonic dilatation (> 6 cm), those whose clinical and laboratory measurements deteriorate and those who do not respond after 7–10 days' maximal medical treatment usually require urgent surgery. Subtotal colectomy with ileostomy is the operation of choice and can be performed open or laparoscopically, dependent upon local expertise. The surgical and medical teams should liaise early in the disease course and, if possible, the patient should have the opportunity to speak with the stoma nurse prior to colectomy.

Maintenance of remission

Life-long maintenance therapy is recommended for all patients with left-sided or extensive disease, but is not necessary in those with proctitis (although 20% of these patients will develop proctitis ‘extension’ over the lifetime of their disease). Once-daily oral 5-aminosalicylates are the preferred first-line agents. Sulfasalazine has a higher incidence of side-effects, but is equally effective and can be considered in patients with coexistent arthropathy. Patients who frequently relapse despite aminosalicylate drugs have in the past always been offered thiopurines (azathioprine or 6-mercaptopurine). While thiopurines still have an important role for treatment, other immunosuppressive drugs may also be used. Biologic therapy with anti-TNF antibodies (infliximab, adalimumab or golimumab) can be considered for maintenance treatment in patients with moderate to severe ulcerative colitis. Combination therapy of infliximab with a thiopurine should be used, as it is more effective than monotherapy with infliximab. In patients where anti-TNF treatment has failed, anti-4G7 integrin antibodies (vedolizumab), Janus kinase inhibitors (tofacitinib) and anti-p40 antibodies (ustekinumab), can be considered to maintain remission.

23.69 Monitoring of inflammatory bowel disease (IBD)

- Assess symptoms, including extra-intestinal manifestations
- Examine for abdominal mass or perianal disease
- Perform full blood count, urea and electrolytes, liver function tests, albumin, C-reactive protein (CRP)
- Check haematinics (vitamin B12, folate, iron studies) at least annually
- Check faecal calprotectin (to monitor each disease flare/change in therapy and assess response)
- Perform stool cultures (at each flare to exclude infection)
- Assess mucosal healing: surrogate markers (CRP/calprotectin), small bowel capsule, ileocolonoscopy and/or small bowel magnetic resonance imaging
- Enrol patient in a dedicated IBD clinic (monitoring of stable, uncomplicated patients may be carried out by a nurse or phone clinic)
- Arrange IBD multidisciplinary meeting for acutely ill or complex patients
- Check vaccinations are up to date; live vaccinations may be given at least 4 weeks before starting immunosuppressive therapy and at least 3 months after stopping immunosuppressive therapy. Patients on immunosuppressive therapy should receive influenza and pneumococcal vaccination
- Ensure surveillance colonoscopy is scheduled where appropriate

Crohn’s disease

Principles of management

Crohn’s disease is a progressive condition that may result in stricture or fistula formation if suboptimally treated. It is therefore important to agree long-term treatment goals with the patient; these are to induce remission and then maintain glucocorticoid-free remission with a normal quality of life. Treatment should focus on monitoring the patient carefully for evidence of disease activity and complications (Box 23.69), and ensuring that mucosal healing is achieved.

Induction of remission in mild to moderate disease

Glucocorticoids remain the mainstay of treatment for active Crohn’s disease. The drug of first choice in patients with ileal disease is budesonide, since it undergoes 90% first-pass metabolism in the liver and has very little systemic toxicity. A typical regimen is 8 mg once daily for 4 weeks, with a stepwise reduction of 3 mg every 4 weeks until therapy is stopped. If there is no response to budesonide within 2 weeks, the patient should be switched to prednisolone, which has greater potency. This is typically given in a dose of 40 mg daily, reducing by 5 mg/week over 8 weeks, at which point treatment is stopped. Oral prednisolone in the dose regimen described above is the treatment of choice for inducing remission in colonic Crohn’s disease.

As an alternative to glucocorticoid therapy, enteral nutrition with either an elemental (constituent amino acids) or polymeric (liquid protein) diet may induce remission. Both types of diet are equally effective, but the polymeric one is more palatable when taken by mouth, and this improves adherence. It is particularly effective in children, in whom equal efficacy to glucocorticoids has been demonstrated, and in extensive ileal disease in adults. As well as resting the gut and providing excellent nutritional support, it also has a direct anti-inflammatory effect. It is an effective bridge to urgent staging investigations at first presentation and can be given by mouth or by nasogastric tube. With sufficient explanation, encouragement and motivation, most patients will tolerate it well.

Induction of remission in severe disease

Patients with severe disease can be treated with systemic glucocorticoids. The early introduction of biologics can also be considered, providing that acute perforating complications, such as abscesses, have not arisen. Anti-TNF (infliximab or adalimumab), anti-4G7 integrin (vedolizumab) and anti-p40 (ustekinumab) therapy can be considered as first-line biologics. Patients with evidence of persistently active disease require further maintenance treatment (see below).

Maintenance therapy

Glucocorticoids are not effective at maintaining remission in Crohn’s disease. Immunosuppressive treatment with thiopurines (azathioprine and
 mercaptopurine) may be used as maintenance therapy, but methotrexate is also effective and can be given once weekly, either orally or by subcutaneous injection; subcutaneous administration has better bioavailability. Patients refractory to immunomodulator therapy should be considered for biologic therapy with anti-TNF (infliximab or adalimumab) (Box 23.70), anti-α4β7 integrin (vedolizumab) or anti-β4 (ustekinumab) therapies. Combination therapy of infliximab with a thiopurine should be used, as it is more effective than monotherapy with infliximab. Combination therapy of infliximab with methotrexate may also be used to reduce immunogenicity. In patients who still require glucocorticoids despite optimal treatment with biologics, other options must be considered including surgery.

Cigarette smokers with Crohn’s disease should be strongly counselled to stop smoking at every possible opportunity. Those that do not manage to stop smoking fare much worse, with increased rates of relapse and surgical intervention, with adverse effects of smoking being more pronounced in women than in men. Careful monitoring of disease activity (see Box 23.69) is the key to maintaining sustained remission and preventing the accumulation of bowel damage in Crohn’s disease.

Fistulas and perianal disease

Fistulae may develop in relation to active Crohn’s disease and are often associated with sepsis. The first step is to define the site by imaging (usually MRI of the pelvis). Endoanal ultrasound is another option for assessment, but is limited in patients with luminal stenoses, as well as by local expertise. Surgical exploration by examination under anaesthetic is usually then required, to delineate the anatomy and drain abscesses. Seton sutures can be inserted through fistula tracts to ensure adequate drainage and to prevent future sepsis. Glucocorticoids are ineffective. Use of antibiotics, such as metronidazole and/or ciprofloxacin, can aid healing as an adjunctive treatment. Thiopurines can be used in chronic disease, but do not usually result in fistula healing. Anti-TNF therapy can heal fistulae and perianal disease in many patients and are indicated when the measures described above have been ineffective. Higher trough infliximab drug levels are aimed for in perianal Crohn’s disease. The evidence of benefit in perianal fistulating disease for the newer biologics is presently unclear. Other options for refractory perianal disease are proctectomy or faecal diversion with an upstream stoma.

### Surgical management

**Ulcerative colitis**

Operations are often necessary to deal with fistulae, abscesses and perianal disease, and may also be required to relieve small or large bowel obstruction. In contrast to ulcerative colitis, surgery is not curative and disease recurrence is the rule. The only method that has consistently been shown to reduce post-operative recurrence is smoking cessation. Antibiotics are effective in the short term only. Use of thiotepas post surgery is suggested if there are indicators of a high chance of recurrence, i.e. more than one resection or evidence of penetrating disease, such as fistulae or abscess. Otherwise, it is common to undertake colonoscopy 6 months after surgery to inspect and biopsy the anastomosis and neo-terminal ileum. Patients with endoscopic recurrence are then prescribed immunomodulators or biologics to prevent further complications.

Surgery should be as conservative as possible in order to minimise the loss of viable intestine and to avoid the creation of a short bowel syndrome (p. 771). Obstructing or fluctuating small bowel disease may require resection of affected tissue. Patients who have localised segments of Crohn’s colitis may be managed by segmental resection and/or multiple stricturoplasties, in which the stricture is not resected but instead incised in its longitudinal axis and sutured transversely. Others who have extensive colitis require total colectomy but ileal pouch formation should be avoided because of the high risk of recurrence within the pouch and subsequent fistulae, abscess formation and pouch failure.

Historical datasets show that around 80% of Crohn’s patients undergo surgery at some stage and 70% of these require more than one operation during their lifetime. Clinical recurrence following resectional surgery is present in 50% of all cases at 10 years. Emerging data demonstrate that aggressive medical therapy, coupled with intense monitoring, probably reduces the requirement for surgery substantially.
**IBD in special circumstances**

**Childhood**

Children developing IBD tend to have more extensive disease than adults. Chronic illness in childhood or adolescence may result in impaired growth, metabolic bone disease and delayed puberty. Loss of schooling and social contact, as well as frequent hospitalisation, can have important psychosocial consequences. Treatment is similar to that described for adults and may involve glucocorticoids, immunosuppressive drugs, biologic agents and surgery. However, exclusive enteral nutrition can also be used to induce disease remission in Crohn’s disease, as well as aiding with growth and nutritional status. Monitoring of height, weight and sexual development is crucial. Children with IBD should be managed by specialised paediatric gastroenterologists and transitioned to adult care in dedicated clinics (Box 23.72).

**Pregnancy**

Pregnant women with IBD are best managed in an MDT approach involving an IBD physician and an obstetrician. A woman’s ability to become pregnant is adversely affected by active IBD. Pre-conceptual counselling should focus on optimising disease control. During pregnancy, roughly one-third of women improve, one-third get worse and one-third remain stable with active disease. In the post-partum period, these changes sometimes reverse spontaneously, e.g., improvement during pregnancy is followed by post-partum relapse. Drug therapy, including aminosalicylates, glucocorticoids, thiopurines and biologics can be safely continued throughout pregnancy, but methotrexate and tofacitinib must be avoided, both during pregnancy and pre-conception (Box 23.73). Biologics such as infliximab, adalimumab, vedolizumab and ustekinumab may pass across the placenta and concentrate in the fetus, especially in the last trimester. Some women who are in deep remission may therefore choose to omit their biologics in the last trimester. However, biologics can be safely continued throughout the pregnancy, especially in women with ongoing active disease, at high risk of relapse or when limited treatment options. Breast feeding is recommended in all women and the use of thiopurines and biologics does not preclude women from breast feeding. Thiopurine drug levels in breast milk are very low, with negligible levels measured in breast-fed infants of mothers on thiopurines. Levels of biologics are also very low in breast milk and lead to negligible levels in the breast-fed infant due to normal gut digestion. Mode of delivery should be discussed with pregnant women and in the absence of active rectal or perianal fistulating disease, where a caesarean section is recommended, a vaginal delivery is safe.

**Metabolic bone disease**

Patients with IBD are prone to developing osteoporosis due to the effects of chronic inflammation, glucocorticoids, weight loss, malnutrition and malabsorption. Osteomalacia can also occur in Crohn’s disease that is complicated by malabsorption, but is less common than osteoporosis. The risk of osteoporosis increases with age and with the dose and duration of glucocorticoid therapy. Patients should have their fracture risk assessed prior to glucocorticoid therapy. Individuals who receive prolonged (>3 months) or repeated courses of oral glucocorticoid therapy should have bone densitometry assessed. Oral bisphosphonates, in the form of alendronate and risedronate, are commonly used for treatment if required. Denosumab and high dose intravenous bisphosphonates should be avoided in women of childbearing age, due to their unknown effects on the fetus.

**Microscopic colitis**

Microscopic colitis, which comprises two related conditions called lymphocytic colitis and collagenous colitis, has no known cause. Both forms are commoner in women with a mean age of presentation of around 60 years. The presentation is with chronic non-bloody watery diarrhoea. The colonoscopic appearances are normal, but histological examination of biopsies shows a range of abnormalities. It is therefore recommended that biopsies of the right and left colon plus the terminal ileum should be undertaken in all patients undergoing colonoscopy for diarrhoea. An increased number of intraepithelial and lamina propria lymphocytes is noted in both forms of microscopic colitis, with a thickened subepithelial collagen band also noted in collagenous colitis. Microscopic colitis may be associated with autoimmune diseases such as coeliac disease,

---

**23.72 Inflammatory bowel disease in adolescence**

- **Delayed growth and pubertal development:** chronic active inflammation, malabsorption, malnutrition and long-term glucocorticoids contribute to short stature and delayed development, with physical and psychological consequences.
- **Metabolic bone disease:** more common with chronic disease beginning in childhood, resulting from chronic inflammation, dietary deficiency and malabsorption of calcium and vitamin D.
- **Drug side-effects and adherence issues:** young people are more likely to require azathioprine or biologic therapy than adults. Poor adherence to therapy is more common than with adults, as younger patients may feel well, lack self-motivation to adhere and believe that drugs are ineffective or cause side-effects.
- **Loss of time from education:** physical illness, surgery, fatigue in chronic inflammatory bowel disease, priority and dignity issues, and social isolation may all contribute.
- **Emotional difficulties:** may result from challenges in coping with illness, problems with forming interpersonal relationships, and issues relating to body image or sexual function.

---

**23.73 Pregnancy and inflammatory bowel disease (IBD)**

### Pre-conception

- Outcomes are best when pregnancy is carefully planned and disease is in remission
- Methotrexate must be stopped 6 months prior to conception; other IBD drugs should be continued until discussed with a specialist
- Aminosalicylates and azathioprine are safe in pregnancy
- Glucocorticoids are probably safe
- Biologic therapy (infliximab, adalimumab, vedolizumab, ustekinumab) in pregnancy can continue if established pre-pregnancy
- Tofacitinib should be avoided in pregnancy
- Folic acid (5 mg/day) is recommended pre-conception. Consider high-dose supplements in small bowel Crohn’s disease with low levels despite 5 mg dose

### Pregnancy

- Two-thirds of patients in remission will remain so in pregnancy
- Active disease is likely to remain active
- Severe active disease carries an increased risk of premature delivery and low birth weight
- Perform endoscopy only when absolutely essential for clinical decision-making (ideally in second trimester)
- X-rays can be performed if clinically indicated, but discuss with the radiologist first. Ultrasound is preferable but is operator-dependent. MRI small bowel can be performed without intravenous gadolinium and oral contrast

### Labour

- This needs careful discussion between patient, gastroenterologist and obstetrician
- Normal labour and vaginal delivery are possible for most
- Caesarean section may be preferred for patients with perianal Crohn’s or an illeo-anal pouch to reduce risks of pelvic floor damage, fistulation and late incontinence
- Venous thromboembolism prophylaxis is important if in hospital

### Breastfeeding

- This is safe and does not exacerbate IBD
- Data on the risk to babies from drugs excreted in breast milk are limited; most of these drugs are probably safe
- Patients should discuss breastfeeding and drug therapy with their doctor
rheumatoid arthritis and thyroid disease, and some drug therapies, such as NSAIDs and PPIs. Ulcerative diarrhea has also been reported to be more prevalent in this group. Treatment with budesonide is usually effective for inducing remission. Up to 70% of individuals can relapse and require further treatment, but others can remain symptom free.

**Functional bowel disorders**

Functional gastrointestinal disorders are a common diagnosis in gastroenterology, accounting for around 40% of all referrals to gastroenterology. They are thought to be disorders of brain–gut interaction, with alterations in motility, visceral hypersensitivity, gut microbiota, immune and mucosal function, as well as alterations in central nervous system processing.

**Functional dyspepsia**

Functional dyspepsia can be diagnosed in patients presenting with dyspepsia where organic disease has been excluded. Patients are usually young (<40 years) and women are affected twice as commonly as men. There are subtypes of this condition, with individuals being classified as having postprandial distress syndrome, epigastric pain syndrome or a mixture of both.

**Pathophysiology**

The cause is poorly understood, but probably covers a spectrum of mucosal, motility and psychological factors.

**Clinical features**

Symptoms such as bloating, early satiety, loss of appetite, nausea, vomiting or retching may suggest a diagnosis of postprandial distress syndrome, whereas symptoms of epigastric pain or epigastric burning may suggest a diagnosis of epigastric pain syndrome. Symptoms seen in functional dyspepsia can significantly overlap with symptoms of an organic disease, and alarm features should be sought (see Box 23.15). While patients with functional dyspepsia can experience vomiting, persistent vomiting may suggest an underlying organic disorder. Peptic ulcer disease must be considered, while in older people intra-abdominal malignancy is a prime concern. There are no diagnostic signs, although there may be inappropriate tenderness on abdominal palpation. A drug history should be taken and the possibility of a depressive illness should be considered. Pregnancy should be ruled out in young women before radiological studies are undertaken. Alcohol misuse should be suspected when early-morning nausea and retching are prominent.

**Investigations**

The history will often suggest the diagnosis. All patients should be checked for *H. pylori* infection and patients with alarm features should undergo endoscopy to exclude mucosal disease. While an ultrasound scan may detect gallstones, these are rarely responsible for dyspeptic symptoms, unless the patient has features to suggest biliary pathology.

**Management**

Up to 10% of patients benefit from *H. pylori* eradication therapy and this should be offered to infected individuals. Eradication also removes a major risk factor for peptic ulcers and gastric cancer, but at the cost of a small risk of side-effects and worsening symptoms of underlying gastro-oesophageal reflux disease. Idiosyncratic and restrictive diets are of little benefit but smaller portions and fat restriction may help.

Drug treatment is targeted on the subtype of functional dyspepsia. Prokinetic drugs (e.g. metoclopramide), fundus-relaxing drugs (e.g. buspirone) or centrally acting neuromodulators (e.g. mirtazapine) can be used in postprandial distress syndrome. Acid suppression medication (e.g. PPI) and tricyclic antidepressants (e.g. amitriptyline) may be used in epigastric pain syndrome. Patients with major psychological disorders that result in persistent or recurrent symptoms may require behavioural or other formal psychotherapy (Ch. 31).

**Functional causes of vomiting**

Cyclical vomiting syndrome (CVS) is an increasingly recognised cause of functional vomiting. It is characterised by distinct phases. There tends to be a prodrome phase, where symptoms of nausea, pallor and sweating are noted. This is then followed by an intense vomiting phase, with other associated symptoms such as abdominal pain, which can last up to a week. After this, patients enter a recovery phase, with improvement and resolution of symptoms. There will then be a period of time without symptoms. Triggers can include stress, fatigue and menstruation. The cause of CVS is unknown, although an association with migraine headaches is recognised. A subset of adults with CVS have symptoms triggered by chronic cannabis use, known as cannabinoid hyperemesis syndrome. Patients with CVS are managed with general lifestyle advice, with avoidance of triggers such as cannabis. Acute episodes can be managed with medications, such as antiemetics (e.g. lorazepam) and antiemetics (e.g. ondansetron). Prophylactic treatment includes the use of tricyclic antidepressants (e.g. amitriptyline) and antiepileptic medication (e.g. levetiracetam).

In all patients it is essential to exclude other common causes of vomiting (see Fig. 23.18). Patients who do not have characteristic symptoms seen in CVS, with nausea or vomiting occurring weekly, in the absence of organic disease may be diagnosed as having chronic nausea and vomiting syndrome (CNVS). These patients may respond to treatments including antiemetics (e.g. ondansetron) and tricyclic antidepressants (e.g. amitriptyline).

**Irritable bowel syndrome**

Irritable bowel syndrome (IBS) has an estimated worldwide prevalence of around 5%. It is characterised by recurrent abdominal pain in association with abnormal defecation in the absence of a structural abnormality of the gut. IBS accounts for frequent absenteeism from work and impaired quality of life. Young women are affected more often than men.

**Pathophysiology**

The cause of IBS is incompletely understood but biopsychosocial factors are thought to play an important role, along with luminal factors, such as diet and the gut microbiota, as discussed below.

**Behavioural and psychosocial factors**

Early learning difficulties or emotionally challenging interactions during childhood may contribute to IBS in later life. Most patients seen in general practice do not have psychological problems but about 50% of patients referred to hospital have a psychiatric illness, such as anxiety, depression, somatisation and neurosis. Panic attacks are also common. Acute psychological stress and overt psychiatric disease are known to alter visceral perception and gastrointestinal motility. There is an increased prevalence of abnormal illness behaviour, with frequent consultations for minor symptoms and reduced coping ability (Ch. 31). These factors contribute to but do not cause IBS.

**Physiological factors**

The pathophysiology of IBS is still not fully understood. IBS is thought to be a disorder of the brain–gut axis, with alterations in visceral hypersensitivity. There is some evidence that IBS may be a serotoninergic (5-HT) disorder, as evidenced by relatively excessive release of 5-HT in diarrhoea-predominant IBS (IBS-D) and relative deficiency with constipation-predominant IBS (IBS-C). Accordingly, 5-HT receptors antagonists are effective in IBS-D, while 5-HT3 agonists improve bowel function in IBS-C. There is some evidence that IBS may represent a state of low-grade gut inflammation or immune activation, not detectable by tests, with raised numbers of mucosal mast cells that sensitize enteric neurons by releasing histamine and tryptase. Some patients respond positively to mast cell stabilisers,
such as ketotifen, which supports a pathogenic role of mast cells in at least some patients. Immune activation may be associated with altered CNS processing of visceral pain signals. This is more common in women and in IBS-D, and may be triggered by a prior episode of gastroenteritis with Salmonella or Campylobacter species.

**Luminal factors**

Both quantitative and qualitative alterations in intestinal bacterial microbiota have been reported. Small intestinal bacterial overgrowth (SIBO) may be present in some patients and lead to symptoms. This “gut dysbiosis” may explain the response to probiotics or the non-absorbable antibiotic rifaximin.

Dietary factors are also important. Some patients have chemical food intolerances (not allergy) to poorly absorbed, short-chain carbohydrates (lactose, fructose and sorbitol, among others), collectively known as FODMAPs (fermentable oligo-, di- and mono-saccharides, and polyols). Whilst their fermentation in the colon is normal physiology, this leads to bloating, pain, wind and altered bowel habit in patients with IBS, thought to be due to visceral hypersensitivity. Gluten exposure seems to cause symptoms in some IBS patients and there is an overlap with the diagnosis of non-coeliac gluten sensitivity (non-celiac serology and normal duodenal biopsies).

**Clinical features**

The key symptoms of IBS include recurrent abdominal pain and altered bowel habit (Box 23.74). Abdominal pain is usually colicky or cramping in nature, felt in the lower abdomen and related to defecation. The bowel habit is variable, with IBS stratified by predominant bowel habit; those with mainly constipation (IBS-C), mainly diarrhoea (IBS-D), mixed bowel habit (IBS-M) or unsubtyped (IBS-U). Those with constipation tend to pass infrequent pelleted stools, usually in association with abdominal pain or proctalgia. Those with diarrhoea have frequent defecation but produce low-volume stools and rarely have nocturnal symptoms. Passage of mucus is common but rectal bleeding does not occur. Patients do not lose weight and are constitutionally well. Diagnosis is made through a careful history, exploring diet, medical, surgical and psychological history. The presence of other functional gastrointestinal disorders may also support the diagnosis, in addition to non-gastrointestinal symptoms such as migraine headaches, dyspareunia and interstitial cystitis. Onset after gastroenteritis may point towards a diagnosis of post-infectious IBS. Physical examination is generally unremarkable, with the exception of variable tenderness to palpation.

**Investigations**

The diagnosis is clinical in nature and can be made confidently in most patients using the Rome IV criteria, combined with the absence of alarm symptoms and without resorting to complicated tests (Box 23.75). Limited laboratory tests are normally performed prior to making a diagnosis of IBS, including full blood count, faecal calprotectin and C-reactive protein, which are all normal. Colonoscopy should be undertaken when patients present with alarm features, to exclude other diagnoses such as colorectal cancer and inflammatory bowel disease. Those who present atypically require investigations to exclude other gastrointestinal diseases. Diarrhoea-predominant patients justify investigations to exclude coeliac disease, microscopic, lactose intolerance, bile acid diarrhoea (see earlier in this chapter), thyrotoxicosis (Ch. 20) and, in relevant countries, parasitic infection.

**Management**

The most important steps are to make a positive diagnosis, as well as educating and reassuring the patient. Communicating diagnostic certainty is crucial, to prevent further unwarranted testing. Many people are concerned that they have developed cancer. A cycle of anxiety leading to colonic symptoms, which further heighten anxiety, can be broken by explaining that symptoms are not due to a serious underlying disease, but instead are the result of behavioural, psychosocial, physiological and luminal factors. In individuals who fail to respond to reassurance, treatment is traditionally tailored to the predominant symptoms (Fig. 23.67).

A large proportion of IBS patients report symptoms triggered by food, with diet being shown to be an effective management option for many patients (Box 23.76). Dietary advice should be implemented under the expert guidance of a dietitian, to prevent potential nutritional deficiencies of restrictive diets. General dietary advice is the first-line option recommended in the UK, with advice on regular meals, adjustment of fibre intake, adequate fluid intake, assessment of alcohol and caffeine intake, decreasing fat intake and assessing components of spicy meals which may be contributing to symptoms. If these measures fail, a low FODMAP diet may help some patients, as may a trial of a gluten-free diet. Up to 30% may benefit from a wheat-free diet, some may respond to lactose exclusion and excess intake of artificial sweeteners, such as sorbitol, should be addressed. Probiotics, in capsule form, may be effective if taken for several months, although the optimum combination of bacterial strains and dose have yet to be clarified.

Patients with intractable symptoms sometimes benefit from several months of therapy with a tricyclic antidepressant, such as amitriptyline or imipramine. Side-effects include dry mouth and drowsiness, but these are usually mild and the drug is generally well tolerated, although patients with features of somatisation tolerate the drug poorly and lower doses should be used. It may act by reducing visceral sensation and by altering gastrointestinal motility. Anxiety and affective disorders may also require specific treatment (Ch. 31). The 5-HT₄ agonist prucalopride, the guanylate cyclase-C receptor agonist linaclotide and chloride channel activators, such as lubiprostone, can be effective in IBS-C.

Systemic and nonabsorbable antibiotics, such as rifaximin, that act strictly on the gut lumen are sometimes used to manage symptoms, although the mechanism of action remains uncertain.

Psychological interventions, such as cognitive behavioural therapy, relaxation and gut-directed hypnotherapy, should be reserved for the most difficult cases. Cognitive behavioural therapy is the most widely studied psychotherapy treatment for IBS and may improve bowel symptoms, quality of life and psychological distress. A range of complementary and alternative therapies exist; most lack a good evidence base but are popular and help some patients (Box 23.77).

Most patients have a relapsing and remitting course. Exacerbations often follow stressful life events, occupational dissatisfaction and difficulties with interpersonal relationships.

### Ischaemic gut injury

Ischaemic gut injury is usually the result of arterial occlusion. Severe hypotension and venous insufficiency are less frequent causes. The presentation is variable, depending on the different vessels involved and the acuteness of the event. Diagnosis is often difficult.
**Acute small bowel ischaemia**

An embolus from the heart or aorta to the superior mesenteric artery is responsible for 40%-50% of cases, thrombosis of underlying atheromatous disease for approximately 25% and non-occlusive ischaemia due to hypotension complicating myocardial infarction, heart failure, arrhythmias or sudden blood loss for approximately 25%. Vasculitis and venous occlusion are rare causes. The clinical spectrum ranges from transient alteration of bowel function to transmural haemorrhagic necrosis and gangrene. Patients usually have evidence of cardiac disease and arrhythmia. Almost all develop abdominal pain that is more impressive than the physical findings. In the early stages, the only physical signs may be a silent, distended abdomen or diminished bowel sounds, with peritonitis developing only later.

Leucocytosis, lactic acidosis, hyperphosphataemia and hyperamylasaeemia are typical. Plain abdominal X-rays show ‘thumb-printing’ due to mucosal oedema. CT with contrast has replaced percutaneous angiography as the gold standard for diagnosis and may demonstrate features such as occlusion of the mesenteric vessels and bowel wall thickening. Laparoscopy may also be used for diagnosis. Resuscitation, management of cardiac disease and intravenous broad-spectrum antibiotic therapy, followed by laparotomy, are key steps. If treatment is instituted...
early, en bloc resection of the bile duct, common duct and liver may salvage some small bowel. In these rare cases, a ‘second look’ laparotomy should be undertaken 24 hours later and further necrotic bowel resected. While laparotomy is the established approach, endovascular techniques may be considered, such as thrombolysis or percutaneous transluminal angioplasty. The results of therapy depend on early intervention; patients treated late have a 75% mortality rate. Survivors often have nutritional failure from short bowel syndrome (Ch. 22) and require intensive nutritional support, including home parenteral nutrition and anticoagulation. Small bowel transplantation can be considered in selected patients. Patients with mesenteric venous thrombosis also require surgery if there are signs of panitis, but are otherwise treated with anticoagulation. Investigations for underlying prothrombotic disorders should be performed (p. 988).

### Acute colonic ischaemia

The splenic flexure and descending colon have little collateral circulation and lie in ‘watershed’ areas of arterial supply. The spectrum of injury ranges from reversible colopathy to transient colitis, colonic stricture, gangrene and fulminant pancolitis. Arterial thromboembolism is usually responsible, but colonic ischaemia can also follow severe hypotension, colonic volvulus, strangulated hernia, systemic vasculitis or hypercoagulable states. Ischaemia of the descending and sigmoid colon is also a complication of abdominal aortic aneurysm surgery where the inferior mesenteric artery is ligated. The patient is usually an older adult who presents with sudden onset of cramping, left-sided, lower abdominal pain and rectal bleeding. Symptoms usually resolve spontaneously over 24–48 hours and healing occurs in 2 weeks. Some may develop a fibrous stricture or segment of colitis. A minority develop gangrene and panitis. CT with contrast is the imaging of choice for diagnosis, with early colonoscopy within 48 hours of presentation recommended; otherwise, mucosal ulceration may have resolved. Resection is required for panitis; colonoscopy should not be performed in this circumstance.

### Chronic mesenteric ischaemia

This results from atherosclerotic stenosis of the coeliac axis, superior mesenteric artery and inferior mesenteric artery. At least two of the three vessels must be affected for symptoms to develop. The typical presentation is with dull but severe mid- to upper abdominal pain developing about 30 minutes after eating. Weight loss is common because patients are reluctant to eat and some experience diarrhoea. Physical examination reveals evidence of generalised arterial disease. An abdominal bruit is sometimes audible but is non-specific. The diagnosis is made by mesenteric angiography. Treatment is by vascular reconstruction or percutaneous angioplasty and stenting, if the patient’s clinical condition permits. The condition is frequently complicated by intestinal infarction, if left untreated.

### Diseases of the pancreas

#### Acute pancreatitis

Acute pancreatitis accounts for 3% of all cases of abdominal pain admitted to hospital. It affects 2–28 per 100,000 of the population and is increasing in incidence. It is a potentially serious condition with an overall mortality of 10%. About 80% of all cases are mild and have a favourable outcome. Approximately 98% of deaths from pancreatitis occur in the 20% of patients with severe disease and about one-third of these arise within the first week, usually from multi-organ failure. After this time, the majority of deaths result from sepsis, especially that complicating infected necrosis. At admission, it is possible to predict patients at risk of these complications (Box 23.78). Individuals who are predicted to have severe pancreatitis (Box 23.79) and those with necrosis or other complications should be managed in a specialist centre with an intensive care unit and multidisciplinary hepatobiliary specialists.

### Pathophysiology

Acute pancreatitis occurs as a consequence of premature intracellular trypsinogen activation, releasing proteases that digest the pancreas and surrounding tissue. Triggers for this are many, including alcohol, gallstones and pancreatic duct obstruction (Fig. 23.68). There is simultaneous activation of nuclear factor kappa B (NFκB), leading to mitochondrial dysfunction, autophagy and a vigorous inflammatory response. The normal pancreas has only a poorly developed capsule, and adjacent structures, including the common bile duct, duodenum, splenic vein and transverse colon, are commonly involved in the inflammatory process. The severity of acute pancreatitis is dependent on the balance between the activity of released proteolytic enzymes and antiproteolytic factors. The latter comprise an intracellular pancreatic trypsin inhibitor protein and circulating β2-macroglobulin, α1-antitrypsin and C1-esterase inhibitors. The causes of acute pancreatitis are listed in Box 23.80. Acute pancreatitis is often self-limiting, but in some patients with severe disease, local complications, such as necrosis, pseudocyst or abscess, occur, as well as systemic complications that lead to multi-organ failure.

#### Clinical features

The typical presentation is with severe, constant upper abdominal pain, of increasing intensity over 15–60 minutes, which radiates to the back. Nausea and vomiting are common. There is marked epigastric tenderness, but in the early stages (and in contrast to a perforated peptic ulcer), guarding and rebound tenderness are absent because the inflammation is principally retroperitoneal. Bowel sounds become quiet or absent as paralytic ileus develops. In severe cases, the patient becomes hypoxic and develops hypovolaemic shock with oliguria. Discoloration of the flanks (Grey Turner’s sign) or the periumbilical region
(Cullen’s sign) is a feature of severe pancreatitis with haemorrhage. The differential diagnosis includes a perforated viscus, acute cholecystitis and myocardial infarction. Various complications may occur and these are listed in Box 23.81.

A collection of fluid and debris may develop in the lesser sac, following inflammatory rupture of the pancreatic duct; this is known as a pancreatic fluid collection. It is initially contained within a poorly defined, fragile wall of granulation tissue, which matures over a 6-week period to form a fibrous capsule (Fig. 23.69). Such ‘pseudocysts’ are common and usually asymptomatic, resolving as the pancreatitis recovers. Pseudocysts greater than 6 cm in diameter seldom disappear spontaneously and can cause constant abdominal pain and compress or erode surrounding structures, including blood vessels, to form pseudoaneurysms. Large pseudocysts can be detected clinically as a palpable abdominal mass.

Pancreatic ascites occurs when fluid leaks from a disrupted pancreatic duct into the peritoneal cavity. Leakage into the thoracic cavity can result in a pleural effusion or a pleuro-pancreatic fistula.

**Investigations**

The diagnosis is based on raised serum amylase or lipase concentrations and ultrasound or CT evidence of pancreatic swelling. Plain X-rays should be taken to exclude other diagnoses, such as perforation or

</table>
obstruction and to identify pulmonary complications. Amylase is efficiently excreted by the kidneys and concentrations may have returned to normal if measured 24–48 hours after the onset of pancreatitis. A persistently elevated serum amylase concentration suggests pseudocyst formation. Peritoneal amylase concentrations are massively elevated in pancreatic ascites. Serum amylase concentrations are also elevated (but less so) in intestinal ischaemia, perforated peptic ulcer and ruptured ovarian cyst, while the salivary isoenzyme of amylase is elevated in parotitis. If available, serum lipase measurements are preferable to amylase, as they have greater diagnostic accuracy for acute pancreatitis.

Ultrasound scanning can confirm the diagnosis, although in the earlier stages the gland may not be grossly swollen. An ultrasound scan is also useful because it may show gallstones, biliary obstruction or pseudocyst formation.

Contrast-enhanced pancreatic CT performed at least 3 days after admission can be useful in assessing viability of the pancreas if persistent organ failure, sepsis or clinical deterioration is present, since these features may indicate that pancreatic necrosis has occurred. Necrotising pancreatitis is associated with decreased pancreatic enhancement on CT, following intravenous injection of contrast material. The presence of gas within necrotic material (Fig. 23.70) suggests infection and impending abscess formation, in which case percutaneous aspiration of material for bacterial culture should be carried out and appropriate antibiotics prescribed. Involvement of the colon, blood vessels and other adjacent structures by the inflammatory process is best seen on CT.

Certain investigations stratify the severity of acute pancreatitis and have important prognostic value at the time of presentation (see Boxes 23.78 and 23.79). In addition, serial assessment of CRP is a useful indicator of progress. A peak CRP of > 210 mg/L in the first 4 days predicts severe acute pancreatitis with 80% accuracy. It is worth noting that the serum amylase concentration has no prognostic value.

Management

Management comprises several related steps:

- establishing the diagnosis and disease severity
- early resuscitation, according to whether the disease is mild or severe
- detection and treatment of complications
- treatment of the underlying cause.

Opiate analgesics should be given to treat pain and hypovolaemia should be corrected using normal saline or other crystalloids. All severe cases should be managed in a high-dependency or intensive care unit. A urinary catheter should be inserted in patients with shock, with a central venous line inserted if required. Oxygen should be given to hypoxic patients and those who develop systemic inflammatory response syndrome (SIRS) may require ventilatory support. Hyperglycaemia should be corrected using insulin and hypocalcaemia by intravenous calcium injection.

Nasogastric aspiration is required only if paralytic ileus is present. Enteral feeding, if tolerated, should be started at an early stage in patients with severe pancreatitis because they are in a severely catabolic state and need nutritional support. Enteral feeding decreases endotoxiaemia and so may reduce systemic complications. Nasojejunal feeding is just as effective as feeding by the nasojejunal route. Prophylaxis of thromboembolism with subcutaneous low-molecular-weight heparin is also advisable. The use of prophylactic, broad-spectrum intravenous antibiotics to prevent infection of pancreatic necrosis is not indicated, but infected necrosis is treated with antibiotics that penetrate necrotic tissue, e.g. carbapenems or quinolones, and metronidazole.

Patients who present with cholangitis in association with severe acute pancreatitis should undergo urgent ERCP to diagnose and treat choledocholithiasis. In less severe cases of gallstone pancreatitis, biliary imaging (using MRCP or EUS) can be carried out after the acute phase has resolved. If the liver function tests return to normal and ultrasound has not demonstrated a dilated biliary tree, laparoscopic cholecystectomy with an on-table cholangiogram is appropriate because any common bile duct stones have probably passed. When the operative cholangiogram detects residual common bile duct stones, these should be removed by laparoscopic exploration of the duct or by post-operative ERCP. Cholecystectomy should be undertaken within 2 weeks of resolution of pancreatitis and preferably during the same admission – to prevent further potentially fatal attacks of pancreatitis. Patients with infected pancreatic necrosis or pancreatic abscess require urgent endoscopic drainage or minimally invasive retroperitoneal pancreatic (MIRP) necrosectomy to debride all cavities of necrotic material. Pancreatic pseudocysts can be treated by drainage into the stomach or duodenum. This is usually performed after an interval of at least 6 weeks, once a pseudocapsule has matured, by surgical or endoscopic cystogastrostomy.

**Chronic pancreatitis**

Chronic pancreatitis is a chronic inflammatory disease characterised by fibrosis and destruction of exocrine pancreatic tissue. Diabetes mellitus occurs in advanced cases because the islets of Langerhans are involved (Ch. 21).

**Pathophysiology**

Around 80% of cases in Western countries result from alcohol misuse, with idiopathic chronic pancreatitis being the second most common cause. In southern India, severe chronic fibrocalcific pancreatitis occurs in non-alcoholics, possibly as a result of malnutrition, deficiency of trace elements and micronutrients, and cassava consumption. Other causes are listed in Box 23.82. The pathophysiology of chronic pancreatitis is shown in Figure 23.71.

**Clinical features**

Chronic pancreatitis predominantly affects middle-aged men with alcohol dependence. More than 80% present with abdominal pain. In 50%, this occurs as episodes of ‘acute pancreatitis’, although each attack results in a degree of permanent pancreatic damage. Relentless, slowly progressive chronic pain without acute exacerbations affects 35% of patients, while the remainder have no pain but present with diarrhoea. Pain is due to a combination of increased pressure within the pancreatic ducts and direct involvement of peripancreatic nerves by the inflammatory process. Pain may be relieved by leaning forwards or by drinking alcohol. Approximately one-fifth of patients chronically consume opiate analgesics. Weight loss is common and results from a combination of anorexia, avoidance of food because of post-prandial pain, malabsorption and/or diabetes. Steatorrhoea occurs when more than 90% of the exocrine tissue has been destroyed; protein malabsorption develops only in the most advanced cases. Overall, 30% of patients have (secondary) diabetes, but this figure rises to 70% in those with chronic fibrocalcific
pancreatitis. Physical examination reveals a thin, malnourished patient with epigastric tenderness. Skin pigmentation over the abdomen and back is common and results from chronic use of a hot water bottle (erythema ab igne). Many patients have features of other alcohol- and smoking-related diseases. Complications are listed in Box 23.83.

### Investigations

Investigations (Box 23.84 and Fig. 23.72) are carried out to:

- make a diagnosis of chronic pancreatitis
- define pancreatic function
- demonstrate anatomical abnormalities prior to surgical intervention.

**Clinical course**

- Normal
- Acute pancreatitis
- Recurrent acute pancreatitis
- Chronic pancreatitis

**Fig. 23.71 Pathophysiology of chronic pancreatitis.** Alcohol and other risk factors may trigger acute pancreatitis through multiple mechanisms. The first (or ‘sentinel’) episode of acute pancreatitis initiates an inflammatory response involving T-helper (Th) cells. Ongoing exposure to alcohol drives further inflammation but this is modified by regulatory T cells (Treg) with subsequent fibrosis, via activation of pancreatic stellate cells. A cycle of inflammation and fibrosis ensues, with development of chronic pancreatitis. Alcohol is the most relevant risk factor, as it is involved at multiple steps.
hypoglycaemia (since both insulin and glucagon are absent) and significant morbidity and mortality.

Malabsorption
This is treated by dietary fat restriction (with supplementary medium-chain triglyceride therapy in malnourished patients) and oral pancreatic enzyme supplements. A PPI is added to optimise duodenal pH for pancreatic enzyme activity.

Management of complications
Surgical or endoscopic therapy may be necessary for the management of pseudocysts, pancreatic ascites, common bile duct or duodenal stricture and the consequences of portal hypertension. Many patients with chronic pancreatitis also require treatment for other alcohol- and smoking-related diseases and for the consequences of self-neglect and malnutrition.

Autoimmune pancreatitis
Autoimmune pancreatitis (AIP) is a chronic fibroinflammatory disease of the pancreas that can mimic cancer, but which responds to glucocorticoids. There are two different subtypes, type 1 and type 2 AIP. Type 1 AIP belongs to IgG4-related disorders, which can include various organs such as bile ducts, salivary glands, kidneys, lungs and thyroid glands. Type 2 AIP affects the pancreas only, but is strongly associated with inflammatory bowel disease, particularly ulcerative colitis. AIP can present with obstructive jaundice, weight loss and abdominal pain. Blood tests may reveal increased serum IgG4 in type 1 AIP; with no reliable serological markers for type 2 AIP. Imaging in type 1 AIP may show a diffusely enlarged pancreas, narrowing of the pancreatic duct, and stricture of the lower bile duct. Focal mass-like pancreatic lesions may be seen in type 2 AIP. The symptom response to glucocorticoids is usually good in AIP, but recurrence can occur after initial response, particularly in type 1 AIP, with some patients requiring immunomodulators (e.g. azathioprine) or rituximab.

Congenital abnormalities affecting the pancreas

Pancreas divisum
This is due to failure of the primitive dorsal and ventral ducts to fuse during embryonic development of the pancreas. As a consequence, most of the pancreatic drainage occurs through the smaller accessory ampulla rather than through the major ampulla. The condition occurs in 7%–10% of the normal population and is usually asymptomatic, but some patients develop acute pancreatitis, chronic pancreatitis or atypical abdominal pain.

Annular pancreas
In this congenital anomaly, the pancreas encircles the second/third part of the duodenum, leading to gastric outlet obstruction. Annular pancreas is associated with malrotation of the intestine, atresias and cardiac anomalies.

Cystic fibrosis
This disease is considered in detail on page 510. The major gastrointestinal manifestations are pancreatic insufficiency and meconium ileus. Peptic ulcer and hepatobiliary disease may also occur. In cystic fibrosis, pancreatic secretions are protein- and mucus-rich. The resultant viscous juice forms plugs that obstruct the pancreatic ductules, leading to progressive destruction of acinar cells. Steatorrhoea is universal and the large-volume bulky stools predispose to rectal prolapse. Malnutrition is compounded by the metabolic demands of respiratory failure and by diabetes, which develops in 40% of patients by adolescence.
Nutritional counselling and supervision are important to ensure intake of high-energy foods, providing 120%–150% of the recommended intake for normal subjects. Fats are an important calorie source and, despite the presence of steatorrhoea, fat intake should not be restricted. Supplementary fat-soluble vitamins are also necessary. High-dose oral pancreatic enzymes are required, in doses sufficient to control steatorrhoea and stool frequency. A PPI aids fat digestion by producing an optimal duodenal pH.

Meconium ileus

Mucus-rich plugs within intestinal contents can obstruct the small or large intestine of a newborn child. Meconium ileus is treated by the mucolytic agent N-acetylcysteine, given orally, by Gastrografin enema or by gut lavage using polyethylene glycol. In resistant cases of meconium ileus, surgical resection may be necessary.

Tumours of the pancreas

Adenocarcinoma of the pancreas

Some 90% of pancreatic neoplasms are adenocarcinomas that arise from the pancreatic ducts. These tumours involve local structures and metastasise to regional lymph nodes at an early stage. Most patients have advanced disease at the time of presentation. Neuro-endocrine tumours also arise in the pancreas, but tend to grow more slowly and have a better prognosis; these are discussed in detail on page 691. The incidence of pancreatic adenocarcinoma is higher in high-income countries, affecting 10–15 per 100,000 in Western populations, rising to 100 per 100,000 in those over the age of 70. Men are affected more often than women. The disease is associated with increasing age, smoking, diabetes and chronic pancreatitis. Between 5% and 10% of patients have a genetic predisposition: hereditary pancreatitis, HINPCC and familial atypical mole multiple melanoma syndrome (FAMMM). Overall survival is only 3%–5%, with a median survival of 6–10 months for those with locally advanced disease and 3–5 months if metastases are present.

Clinical features

Many patients are asymptomatic until an advanced stage, when they present with central abdominal pain, weight loss and obstructive jaundice (Fig. 23.73). The pain results from invasion of the coeliac plexus and is characteristically incessant and gnawing. It often radiates from the upper abdomen through to the back and may be eased a little by bending forwards. Almost all patients lose weight and many are cachectic. Around 60%–70% of tumours arise from the head of the pancreas, and involvement of the common bile duct results in the development of obstructive jaundice, often with severe pruritus. Some patients present with diarrhoea, vomiting from duodenal obstruction, diabetes mellitus, recurrent venous thrombosis, acute pancreatitis or depression. Physical examination reveals clear evidence of weight loss. An abdominal mass due to the tumour, a palpable gallbladder or hepatic metastases is commonly found. A palpable gallbladder in a jaundiced patient is usually the consequence of distal biliary obstruction by a pancreatic cancer (Courvoisier’s sign).

Fig. 23.73 Features of pancreatic cancer.
Investigations

The diagnosis is usually made by ultrasound and contrast-enhanced CT (Fig. 23.74). Diagnosis in non-jaundiced patients is often delayed because presenting symptoms are relatively non-specific. Fit patients with small, localised tumours should undergo staging to define operability. EUS or laparoscopy with laparoscopic ultrasound will define tumour size, involvement of blood vessels and metastatic spread. In patients unsuitable for surgery because of advanced disease, frailty or comorbidity, EUS- or CT-guided cytology or biopsy can be used to confirm the diagnosis (see Fig. 23.74). MRCP and ERCP are sensitive methods of diagnosing pancreatic cancer and are valuable when the diagnosis is in doubt, although differentiation between cancer and localised chronic pancreatitis can be difficult. The main role of ERCP is to insert a stent into the common bile duct to relieve obstructive jaundice in inoperable patients. Serum cancer antigen 19-9 (CA 19-9) can be used to monitor response to treatment and as a marker of recurrent disease. It has a poor predictive value for diagnosis.

Management

Surgical resection is the only method of effecting cure and 5-year survival in patients undergoing a complete resection is around 12%. Adjuvant chemotherapy can also be used in these patients, using gemcitabine and capcitabine. Only 10%–15% of tumours are resectable with potential curative intent, since most are locally advanced at the time of diagnosis. For the great majority of patients, treatment is palliative. Chemotherapy with FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan and oxaliplatin) improves median survival to 11 months. Pain relief can be achieved using analgesics, but in some patients coeliac plexus neurolysis may be required. Jaundice can be relieved by cholecdochogastrostomy in fit patients, whereas percutaneous or endoscopic stenting is preferable in older patients and those with very advanced disease. Ampullary or periampullary adenocarcinomas are rare neoplasms that arise from the ampulla of Vater or adjacent duodenum. They are often polypoid and may ulcerate; they frequently infiltrate the duodenum, but behave less aggressively than pancreatic adenocarcinoma. Around 25% of patients undergoing resection of ampullary or periampullary tumours survive for 5 years, in contrast to patients with pancreatic ductal cancer.

Incidental pancreatic mass

Cystic neoplasms of the pancreas are increasingly being seen with widespread use of CT. These are a heterogeneous group; serous cystadenomas rarely, if ever, become malignant and do not require surgery. Mucinous cysts occur more often in women, are usually in the pancreatic tail and display a spectrum of behaviour from benign to frankly malignant. Aspiration of the cyst contents for cytology and measurement of CEA and amylase concentrations in fluid obtained at EUS can help determine whether a lesion is mucinous or not. In fit patients, all mucinous lesions should be resected. A variant, called intraductal papillary mucinous neoplasm (IPMN), is often discovered coincidentally on CT, frequently in men in old age. This may affect the main pancreatic duct with marked dilatation and plugs of mucus, or may involve a side branch. The histology varies from villous adenomatous change to dysplasia or carcinoma. Since IPMN is a pre-malignant, but indolent, condition, the decision to resect or to monitor depends on age and fitness of the patient and location, size and evolution of lesions.

Diseases of the peritoneal cavity

Peritonitis

Surgical peritonitis occurs as the result of a ruptured viscus (for details see this book’s companion text, Principles and Practice of Surgery). Peritonitis may also complicate ascites in chronic liver disease (spontaneous bacterial peritonitis, p. 877) or may occur in children in the absence of ascites, due to infection with Streptococcus pneumoniae or β-haemolytic streptococci (p. 301).

Chlamydial peritonitis is a complication of pelvic inflammatory disease (p. 375). The patient presents with right upper quadrant pain, pyrexia and a hepatic rub (the Fitz-Hugh–Curtis syndrome). Tuberculosis may cause peritonitis and ascites (p. 518).

Tumours

The most common is secondary adenocarcinoma from the ovary or gastrointestinal tract. Mesothelioma is a rare tumour complicating asbestos exposure. It presents as a diffuse abdominal mass, due to omental infiltration, and with ascites. The prognosis is extremely poor. Pseudomyxoma peritonei is a rare tumour of the appendix that spreads into the peritoneal cavity and is often found incidentally. Diagnosis can be confirmed by abdominal CT or MRI, with cytoreductive surgery and hyperthermic intra-peritoneal chemotherapy being used for curative treatment.

Other disorders

Endometriosis

Ectopic endometrial tissue can become embedded on the serosal aspect of the intestine, most frequently in the sigmoid and rectum. The overlying mucosa is usually intact. Cyclical engorgement and inflammation result in pain, bleeding, diarrhoea, constipation and adhesions or
obstruction. Low backache is frequent. The onset is usually between 20 and 45 years and the condition is more common in nulliparous women. Bimanual examination may reveal tender nodules in the pouch of Douglas. Endoscopic studies reveal the diagnosis only if carried out during menstruation, when a bluish mass with intact overlying mucosa is apparent. In some patients, laparoscopy is required. Treatment options include laparoscopic diathermy and hormonal therapy with progestogens (e.g. norethisterone), gonadotrophin-releasing hormone analogues or danazol.

**Pneumatosis cystoides intestinalis**

In this rare condition, multiple gas-filled submucosal cysts line the colonic and small bowel walls. The cause is unknown but the condition may be seen in patients with chronic cardiac or pulmonary disease, pyloric obstruction, systemic sclerosis or dermatomyositis. Most patients are asymptomatic, although there may be abdominal cramp, diarrhoea, tenesmus, rectal bleeding and mucus discharge. The cysts are recognised on sigmoidoscopy, plain abdominal X-rays, CT or MRI. Therapies reported to be effective include prolonged high-flow oxygen, elemental diets and antibiotics.

**HIV/AIDS and the gastrointestinal tract**

Patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) may develop several symptoms referable to the gastrointestinal tract, as discussed in detail on page 359. HIV testing should be considered in all patients with atypical or unexplained gastrointestinal symptoms and in those resident in areas of high prevalence.

Multiple Choice Questions

23.1. A 27-year-old woman with coeliac disease presents with ongoing symptoms of chronic diarrhoea despite being on a gluten-free diet. Bloods tests for tTG are taken, which are elevated. Which would be the next appropriate test?

A. Capsule endoscopy  
B. Colonoscopy  
C. Endoscopy with duodenal biopsies  
D. CT abdomen  
E. Lactose hydrogen breath test

Answer: C.

The most likely cause of symptoms in this patient is ongoing disease activity from coeliac disease. The gold standard of assessment of adherence in coeliac disease is an endoscopy with duodenal biopsies. Other causes of diarrhoea are also possible, and investigations such as a colonoscopy may be later considered, provided that there is no ongoing villous atrophy on biopsy.

23.2. A 72-year-old man presents with a 24-hour history of haematemesis. He receives resuscitation prior to a planned endoscopy. Which of the medications below should he continue to take if possible?

A. Rivaroxaban  
B. Warfarin  
C. Clopidogrel  
D. Aspirin  
E. Prasugrel

Answer: D.

Low-dose aspirin (75 mg) can be continued during an upper gastrointestinal bleed. Caution should be taken with discontinuation, in view of an increased association of cardiovascular and cerebrovascular events noted within one week of discontinuation. Whilst bleeding risk may be increased during an upper GI bleed with aspirin, all-cause mortality is reduced with continuation. Direct oral anticoagulants, P2Y12-receptor antagonists and warfarin should be discontinued in most cases, although balance and risks may need to be evaluated, such as the continuation of dual antiplatelets (aspirin and clopidogrel) being considered for patients with drug-eluting coronary artery stents.

23.3. A 28-year-old pregnant woman with known pan-ulcerative colitis presents to clinic. Her most recent colonoscopy prior to pregnancy showed severe active colonic disease both macroscopically and histologically. She is 30 weeks pregnant and currently is taking infliximab for management of her ulcerative colitis, opening her bowels 4 times per day. What is the most appropriate ongoing management?

A. Commence methotrexate in addition to infliximab  
B. Switch to vedolizumab  
C. Discontinue infliximab and restart post-partum  
D. Discontinue infliximab and restart in future if has symptoms  
E. Continue with infliximab during remainder of pregnancy

Answer: E.

The best course of action in this circumstance would be to continue with infliximab during her third trimester. Women with moderate to active disease can experience disease activity during pregnancy, which can be associated with low birth weight and preterm birth. Despite significant exposure of the fetus to anti-TNF drugs during the third trimester, no negative impact on neonatal outcomes or pregnancy has been shown. In individuals with inactive disease, it may be reasonable to discontinue TNF therapy during the third trimester. Patients must be counselled on the risks and benefits during pregnancy. There is no indication for changing class of drug at this point, with methotrexate being shown to be teratogenic.

23.4. A 28-year-old man with a background of asthma presents with a history of intermittent dysphagia to solids and liquids, in addition to chest pain. An endoscopy is performed which shows longitudinal furrows and exudate in the oesophagus. Oesophageal biopsies demonstrate 25 eosinophils/HPF. What is the most appropriate initial pharmacological management?

A. Amitriptyline  
B. 8-week empirical trial of PPI  
C. Swallowed fluticasone  
D. Oral budesonide  
E. Inhaled salbutamol

Answer: B.

The most likely diagnosis in this man is eosinophilic oesophagitis. An empirical 8-week trial of PPIs should be used in the first instance, with around one-third of patients responding, known as PPI-responsive oesophageal eosinophilia. In individuals who fail to respond to this, 8–12 weeks of topical therapy with glucocorticoids can be used, such as fluticasone or budesonide. In addition, dietary modifications are an effective management strategy, including elemental and elimination diets.

23.5. A 55-year-old female with a history of chronic constipation presents having failed to respond to fibre supplements, lactulose and bisacodyl. In view of this, anorectal manometry is performed, suggesting dyssynergic defecation. What is the next appropriate management step?

A. Low FODMAP diet  
B. Reassurance  
C. Biofeedback  
D. Lincalotide  
E. Prucalopride

Answer: C.

Biofeedback therapy has been shown to be an effective management option in individuals with dyssynergic defecation, with up to 70% of individuals responding to this therapy. Agents such as lincalotide and prucalopride may be considered in individuals with functional or slow transit constipation. It is worth noting that patients with dyssynergic defecation may have secondary slow transit constipation, which may respond to pharmacological management. However, biofeedback would be the first-line management for dyssynergic defecation.

- Encephalopathy
- Weight loss
- Scratch marks from itching

History and significance of abdominal signs

i Interpretation of physical signs in cirrhosis

Signs of cirrhosis
- Spider naevi
- Palmar erythema
- Leuconychia
- Bruising (low platelets)
- Loss of body hair (increased oestrogens)
- Gynaecomastia (increased oestrogens)

Signs of portal hypertension
- Splenomegaly
- Dilated abdominal wall veins

Signs of decompensation
- Jaundice
- Ascites/peripheral oedema
- Flapping tremor (encephalopathy)

Signs related to specific aetiologies
- Dupuytren’s contracture (alcohol)
- Parotid swelling (alcohol)
- Intoxication/withdrawal (alcohol)
- Xanthelasma (PBC, NAFLD)
- Scratch marks (cholestatic liver disease)
- Clubbing (hepatopulmonary syndrome)

(NAFLD = non-alcoholic fatty liver disease; PBC = primary biliary cholangitis)

Silent presentation of liver disease

It is important to note that patients with liver disease can present silently following detection of abnormality on screening investigation. This occurs frequently in practice in three settings:

Biochemical abnormality
- Liver enzyme abnormality detected during health screening or drug monitoring

Radiological abnormality
- Observation of an unexpected structural abnormality such as an altered liver texture or contour, or a mass lesion on ultrasound, computed tomography or other imaging undertaken for reasons unrelated to the liver

Serological abnormality
- Detection of a liver-related autoantibody

Ascites

Causes
- Exudative (high protein)
  - Carcinoma
  - Tuberculosis
- Transudative (low protein)
  - Cirrhosis
  - Renal failure (including nephrotic syndrome)
  - Congestive heart failure

Associated clinical findings
- Weight loss
- Abdominal mass
- ‘Craggy’ hepatomegaly
- Weight loss ± fever
- Stigma of cirrhosis (see above)
- Severe generalised oedema
- Elevated jugular venous pressure
- Peripheral oedema

Assessment of liver size

Clinical assessment of hepatomegaly is important in diagnosing liver disease.
- Start in the right iliac fossa.
- Press hand gently up towards ribcage as patient breathes in.
- Progress up the abdomen 2 cm with each breath.
- Detect if smooth or irregular, tender or non-tender; ascertain the shape.
- Confirm the lower border of the liver by percussion.
- Identify the upper border by percussion.

Assessment of encephalopathy

Flapping tremor. Jerky forward movements every 5–10 secs, when arms are outstretched and hands are dorsiflexed, suggest hepatic encephalopathy. The movements are coarser than those seen in tremor.

Number connection test. These 25 numbered circles can normally be joined together within 30 secs. Serial observations may provide useful information, as long as the position of the numbers is varied to avoid the patient learning their pattern.

Constructional apraxia. Drawing stars and clocks may reveal marked abnormality.
Functional anatomy and physiology

Applied anatomy

Normal liver structure and blood supply

The liver weighs 1.2–1.5 kg and has multiple functions, including roles in metabolism, control of infection, and elimination of toxins and by-products of metabolism. It is classically divided into left and right lobes by the falciform ligament, but a more useful functional division is into the right and left hemilivers, based on blood supply (Fig. 24.1). These are further divided into eight segments, according to subdivisions of the hepatic and portal veins. Each segment has its own branch of the hepatic artery and biliary tree. The segmental anatomy of the liver has an important influence on imaging and treatment of liver tumours, given the increasing use of surgical resection. A liver segment is made up of multiple smaller units known as lobules, comprised of a central vein, radiating sinusoids separated from each other by single liver cell (hepatocyte) plates, and peripheral portal tracts containing terminal branches of the hepatic artery, portal vein and bile duct. The functional unit of the liver is the hepatic acinus (Fig. 24.2).

Blood flows into the acinus via a single branch of the portal vein and hepatic artery situated centrally in the portal tract. Blood flows outwards along the hepatic sinusoids into one of several tributaries of the hepatic vein at the periphery of the acinus. Bile is excreted by hepatocytes into channels called cholangiocytes, which lie between them, and flows in the opposite direction from the periphery of the acinus back to the interlobular bile duct in the portal tract. The hepatocytes in each acinus lie in three zones, depending on their position relative to the portal tract. Those in zone 1 are closest to the terminal branches of the portal vein and hepatic artery, and are richly supplied with oxygenated blood, and with blood containing the highest concentration of nutrients and toxins. Conversely, hepatocytes in zone 3 are furthest from the portal tracts and closest to the hepatic veins, and are therefore relatively hypoxic and exposed to lower concentrations of nutrients and toxins compared to zone 1. The different perfusion and toxin exposure patterns, and thus vulnerability, of hepatocytes in the different zones contribute to the often patchy nature of liver injury.

Liver cells

Hepatocytes comprise 80% of liver cells. The remaining 20% are the endothelial cells lining the sinusoids, cholangiocytes lining the intrahepatic bile ducts, cells of the immune system including macrophages (Kupffer cells) and key populations of non-parenchymal cells, including hepatic stellate cells (Ito cells) and other myofibroblast precursors.

Endothelial cells line the sinusoids (Fig. 24.3), a network of capillary vessels that differ from other capillary beds in the body, in that there is no basement membrane. The endothelial cells have gaps between them...

**Blood supply**

The liver is unique as an organ, as it has dual perfusion. The majority of its blood supply (50%–90%) is via the portal vein, which drains blood from the gut via the superior mesenteric vein and from the spleen, and is the principal route for nutrient trafficking to the liver. A minority of inflow is oxygenated blood from the hepatic artery. The dual perfusion system, and the variable contribution from portal vein and hepatic artery, can have important effects on the clinical expression of liver ischaemia (which typically exhibits a less dramatic pattern than ischaemia in other organs, a fact that can sometimes lead to it being missed clinically), and can raise practical challenges in liver surgery.

**Biliary system and gallbladder**

Hepatocytes provide the driving force for bile flow by creating osmotic gradients of bile acids, which form micelles in bile (bile acid-dependent bile flow), and of sodium (bile acid-independent bile flow). Hepatocytes secrete bile into the biliary canaliculi that then progressively merge into a system of interlobular, septal and major ducts. The right and left hepatic ducts join as they emerge from the liver to form the common hepatic duct, which becomes the common bile duct after joining the cystic duct (see Fig. 24.2). The common bile duct is approximately 5 cm long and 4–6 mm wide. The distal portion of the duct passes through the head of the pancreas and usually joins the pancreatic duct before entering the duodenum through the ampullary sphincter (sphincter of Oddi). It should be noted, though, that the anatomy of the lower common bile duct can vary widely. Common bile duct pressure is maintained by rhythmic contraction and relaxation of the sphincter of Oddi; this pressure exceeds gallbladder pressure in the fasting state, so that bile normally flows into the gallbladder, where it is concentrated 10-fold by resorption of water and electrolytes.

---

(Continued on the next page.)
The gallbladder is a pear-shaped sac typically lying under the right hemiliver, with its fundus located anteriorly behind the tip of the 9th costal cartilage. Anatomical variation is common. The function of the gallbladder is to concentrate, and provide a reservoir for, bile. Gallbladder tone is maintained by vagal activity, and cholecystokinin released from the duodenal mucosa during feeding causes gallbladder contraction and reduces sphincter pressure, so that bile flows into the duodenum. The body and neck of the gallbladder pass posteroomedially towards the porta hepatis, and the cystic duct then joins to the common hepatic duct. The cystic duct mucosa has prominent crescentic folds (valves of Heister), giving it a beaded appearance on cholangiography.

**Hepatic function**

### Carbohydrate, amino acid and lipid metabolism

The liver plays a central role in carbohydrate, lipid and amino acid metabolism, and is also involved in metabolising drugs and environmental toxins (Fig. 24.5). An important and increasingly recognised role for the liver is in the integration of metabolic pathways, regulating the response of the body to feeding and starvation. Abnormality in metabolic pathways and their regulation can play an important role both in liver disease (e.g. non-alcoholic fatty liver disease, NAFLD) and in diseases that are not conventionally regarded as diseases of the liver (such as type 2 diabetes and inborn errors of metabolism). Hepatocytes have specific pathways to handle each of the nutrients absorbed from the gut and carried to the liver via the portal vein:

- Amino acids from dietary proteins are used for synthesis of plasma proteins, including albumin. The liver produces 8–14 g of albumin per day, and this plays a critical role in maintaining oncotic pressure in the vascular space and in the transport of small molecules like bilirubin, hormones and drugs throughout the body. Amino acids that are not required for the production of new proteins are broken down, with the amino group being converted ultimately to urea.
- Following a meal, more than half of the glucose absorbed is taken up by the liver and stored as glycogen or converted to glycerol and fatty acids, thus preventing hyperglycaemia. During fasting, glucose is synthesised (gluconeogenesis) or released from glycogen (glyco-genolysis) in the liver, thereby preventing hypoglycaemia.
- The liver plays a central role in lipid metabolism, producing very low-density lipoproteins and further metabolising low- and high-density lipoproteins (see Fig. 19.12).

### Clotting factors

The liver produces key proteins that are involved in the coagulation cascade. Many of these coagulation factors (II, VII, IX and X) are post-translationally modified by vitamin K-dependent enzymes, and their synthesis is impaired in vitamin K deficiency. Reduced clotting factor synthesis is an important and easily accessible biomarker of liver function in the setting of liver injury. The short half-life of clotting factors makes it the prothrombin time (PT); or the International Normalised Ratio, INR) a rapid, responsive measure of hepatocyte function. However, the deranged PT or INR seen in liver disease does not directly equate to increased bleeding risk, as these tests do not capture the concurrent reduced synthesis of anticoagulant factors, including protein C and protein S. In stable patients with liver disease the coagulation is rebalanced by these offsetting factors that restore a neutral or marginally pro-thrombotic state (balanced coagulopathy). Correction of PT using blood products before minor invasive procedures should be guided by clinical risk rather than the absolute value of the PT.

### Bilirubin metabolism and bile

The liver plays a central role in the metabolism of bilirubin and is responsible for the production of bile (Fig. 24.6). Between 425 and 510 mmol (250–300 mg) of unconjugated bilirubin is produced from the catabolism of haem daily. Bilirubin in the blood is normally almost all unconjugated and, because it is not water-soluble, is bound to albumin and does not pass into the urine. Unconjugated bilirubin is taken up by hepatocytes at the sinusoidal membrane, where it is conjugated in the endoplasmic reticulum by UDP-glucuronyl transferase, producing bilirubin mono- and diglucuronide. Impaired conjugation by this enzyme is a cause of inherited hyperbilirubinaemias (see Box 24.18). These bilirubin conjugates are water-soluble and are exported into the bile canaliculi by specific carriers on the hepatocyte membranes. The conjugated bilirubin is excreted in the bile and passes into the ductal lumen.

Once in the intestine, conjugated bilirubin is metabolised by colonic bacteria to form stercobilinogen, which may be further oxidised to stercobilin. Both stercobilinogen and stercobilin are then excreted in the stool, contributing to its brown colour. Biliary obstruction results in reduced stercobilinogen in the stool, and the stools become pale. A small amount of stercobilinogen (4 mg/day) is absorbed from the bowel, passes through

---

![Fig. 24.5 Important liver functions.](image1)

![Fig. 24.6 Pathway of bilirubin excretion.](image2)
Investigation of liver and hepatobiliary disease

Investigations play an important role in the management of liver disease in three settings:

- identifying the presence of liver disease in those with risk factors
- establishing the aetiology in those with incidentally found liver disease
- understanding disease severity (in particular, identification of fibrosis which leads to cirrhosis with its complications).

When planning investigations, it is important to be clear as to which of these goals is being addressed.

Suspicion of the presence of liver disease is normally based on blood biochemistry abnormality (‘liver function tests’, or ‘LFTs’).

Aetiology is typically established through a combination of history, specific blood tests and, where appropriate, imaging and liver biopsy.

Staging of disease involves the assessment of fibrosis and identification of cirrhosis and its complications. Although histology remains the gold standard for staging liver fibrosis, it has been largely replaced by non-invasive approaches, including novel imaging modalities, elastography, serum markers of fibrosis and predictive scoring systems.

The aims of investigation in patients with suspected liver disease are shown in Box 24.1.

Liver blood biochemistry

Liver blood biochemistry (LFTs) includes the measurement of serum bilirubin, aminotransferases, alkaline phosphatase, γ-glutamyl transferase and albumin. Most analyses measured by LFTs are not truly ‘function’ tests but enzymes that are released by injured hepatocytes and provide biochemical evidence of liver cell damage. The pattern of liver enzyme abnormalities can help to distinguish the likely cause of injury (hepatitic or cholestatic). Liver function per se is best assessed by the serum bilirubin, albumin and prothrombin time because of the role played by the liver in clearance of bilirubin and in synthesis of albumin and clotting factors. These measures reflect the severity of liver disease.

24.1 Aims of investigations in patients with suspected liver disease

- Detect hepatic abnormality
- Measure the severity of liver damage
- Detect the pattern of liver function test abnormality: hepatitis, cholestatic or mixed
- Identify the specific cause
- Investigate possible complications
and are related to clinical outcomes, reflected by their use in several prognostic scores: the Child–Pugh and MELD (Model for End-stage Liver Disease) scores in cirrhosis (see Boxes 24.31 and 24.32), the Glasgow score in alcoholic hepatitis (see Box 24.49) and the King’s College Hospital criteria for liver transplantation in acute liver failure (see Box 24.18).

### Bilirubin

The degree of elevation of bilirubin can reflect the degree of liver damage. A raised bilirubin often occurs earlier in the natural history of biliary disease (e.g. primary sclerosing cholangitis) than in disease of the liver parenchyma (e.g. cirrhosis), where the hepatocytes are primarily involved. Swelling of the liver within its capsule in inflammation can, however, sometimes impair bile flow and cause an elevation of bilirubin level that is disproportionate to the degree of liver injury. Caution is therefore needed in interpreting the level of liver injury purely on the basis of bilirubin elevation. Bilirubin may also be elevated in the absence of liver injury as a result of haemolysis (resulting in increased bilirubin production) or inherited disorders of bilirubin metabolism (see Box 24.12).

### Albumin

Serum albumin levels are often low in patients with cirrhosis. This is due to a change in the volume of distribution of albumin, and to reduced synthesis. Since the plasma half-life of albumin is about 2 weeks, albumin levels may be normal in acute liver failure but are almost always reduced in chronic liver failure. Albumin is not a specific marker of liver disease and is reduced in a range of conditions, including sepsis, malnutrition, nephrotic syndrome and protein-losing enteropathy.

### Alanine aminotransferase and aspartate aminotransferase

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are intracellular enzymes that are released during damage to hepatocytes. Although AST may also be released from heart or skeletal muscle, expression of ALT outside the liver is relatively low and this enzyme is therefore considered more specific for hepatocellular damage. Large increases of aminotransferase activity favour hepatocellular damage, and this pattern of enzyme abnormality is known as ‘hepatitic’.

The AST level is usually lower than the ALT, resulting in an AST/ALT ratio of less than 0.8. This ratio reverses in two situations: in alcohol-related liver disease (particularly in alcoholic hepatitis where the ratio can be >2), or as an indicator of advanced fibrosis in non-alcohol-related liver disease such as hepatitis C or NAFLD.

### Alkaline phosphatase and γ-glutamyl transferase

Alkaline phosphatase (ALP) is the collective name given to several different enzymes that hydrolyse phosphate esters at alkaline pH. These enzymes are widely distributed in the body but the main sites of production are the liver, bone and placenta. ALPs are post-translationally modified, resulting in the production of several different isoenzymes, which differ in abundance in different tissues. ALP enzymes in the liver are located in cell membranes of the hepatic sinusoids and the biliary canaliculi. Accordingly, levels rise with biliary injury and with sinusoidal obstruction, as occurs in infiltrative liver disease.

Gamma-glutamyl transferase (GGT) is a microsomal enzyme found in many cells and tissues of the body. The highest concentrations are located in the liver, where it is produced by hepatocytes and biliary epithelium.

The pattern of a modest increase in aminotransferase activity and large increases in ALP and GGT activity suggests impaired bile flow and is commonly described as ‘cholestatic’ (Box 24.2). Isolated elevation of the serum GGT is relatively common and may occur during ingestion of microsomal enzyme-inducing drugs, including alcohol (Box 24.3), but also in NAFLD. Elevated ALP with normal GGT is suggestive of non-hepatic origin, e.g. bone disease or pregnancy.

### Other biochemical tests

Other widely available biochemical tests may become altered in patients with liver disease:

- Hyponatraemia occurs in severe liver disease despite a high total body sodium content due to increased production of vasopressin (antidiuretic hormone, ADH; see Fig. 19.7), and may be exacerbated by diuretic use. A low sodium level predicts a poor prognosis in cirrhosis.
- Serum urea may be reduced in hepatic failure or due to loss of muscle mass, whereas levels of urea may be increased following gastrointestinal haemorrhage.
- Ferritin is elevated in patients with haemochromatosis, systemic inflammatory disease and a range of conditions causing significant parenchymal inflammation, including alcohol excess and NAFLD.

---

**Fig. 24.8** Ultrasound showing a stone in the gallbladder (A) with acoustic shadow (S).
Haematological tests

Blood count

The peripheral blood count is often abnormal and can give a clue to the underlying diagnosis:

- A normochromic normocytic anaemia may reflect anaemia of chronic disease or recent gastrointestinal haemorrhage, whereas chronic blood loss is characterised by a hypochromic microcytic anaemia secondary to iron deficiency. A high erythrocyte mean cell volume (macrocytosis) is associated with alcohol misuse or haemolysis, but target cells in any jaundiced patient also result in a macrocytosis.
- Leucopenia may complicate portal hypertension and hypersplenism, whereas leucocytosis may occur with cholangitis, alcoholic hepatitis and hepatic abscesses. Atypical lymphocytes are seen in infectious mononucleosis, which may be complicated by an acute hepatitis.
- Thrombocytopenia is common in cirrhosis and is due to reduced platelet production and increased breakdown because of hypersplenism. Thrombopoietin, required for platelet production, is produced in the liver and levels fall with worsening liver function. Thus platelet levels are usually more depressed than white cells and haemoglobin in the presence of hypersplenism in patients with cirrhosis. Thrombocytosis is unusual in patients with liver disease but may occur in those with active gastrointestinal haemorrhage and, rarely, in hepatocellular carcinoma.

Coagulation tests

These are often abnormal in patients with liver disease. An increased PT is an indicator of impaired liver function. The normal half-lives of the vitamin K-dependent coagulation factors in the blood are short (5–72 hours), and so changes in the PT occur relatively quickly following liver damage; these changes provide valuable prognostic information in patients with both acute and chronic liver failure. Vitamin K does not reverse this deficiency if it is due to liver disease, but will correct the PT if the cause is vitamin K deficiency, as may occur with cholestasis due to malabsorption of fat-soluble vitamins, or poor diet.

24.4 Chronic liver disease screen

- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver autoantibodies (antinuclear antibody, smooth muscle antibody, antimitochondrial antibody, anti-liver–kidney microsomal antibody)
- Immunoglobulins
- Ferritin
- α1-antitrypsin
- Caeruloplasmin

Immunological tests

A variety of tests are available to evaluate the aetiology of hepatic disease (Boxes 24.4 and 24.5). The presence of liver-related autoantibodies can be suggestive of autoimmune liver disease (although false-positive results can occur in other inflammatory diseases such as NASH). Elevation in overall serum immunoglobulin levels (either IgG or IgM) can also indicate autoimmunity. In contrast, elevated serum IgA may be seen in alcohol-related liver disease and NAFLD.

Imaging

Several imaging techniques can be used to determine the site and nature of structural lesions in the liver and biliary tree. In general, however, imaging techniques are unable to identify hepatic inflammation and have poor sensitivity for liver fibrosis unless advanced cirrhosis with portal hypertension is present.

Ultrasound

Ultrasound is non-invasive and most commonly used as a ‘first-line’ test to identify gallstones, biliary obstruction (Fig. 24.3) or thrombosis in the hepatic vasculature. Ultrasound may show changes of cirrhosis (nodular liver contour, coarse echotexture, right lobe atrophy and left lobe hypertrophy) or portal hypertension (splenomegaly, ascites) but has a relatively low sensitivity for diagnosing compensated cirrhosis. Focal lesions, such as tumours, may not be detected if they are less than 2 cm in diameter.

(AlP = alkaline phosphatase; ALT = alanine aminotransferase; AMA = antimitochondrial antibody; ANA = antinuclear antibody; ASMA = anti-smooth muscle antibody; AST = aspartate aminotransferase; HBeAg = antibody to hepatitis B e antigen; HBeAb = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HFE = haemochromatosis (high iron Fe); IgM = immunoglobulin M; IgG = immunoglobulin G; LKM = liver–kidney microsomal antibody; MCV = mean cell volume; MRCP = magnetic resonance cholangiopancreatography)
and have similar echogenicity to normal liver tissue. Bubble-based contrast media can enhance discriminant capability. Doppler ultrasound allows blood flow in the hepatic artery, portal vein and hepatic veins to be investigated. Endoscopic ultrasound provides high-resolution images of the pancreas, biliary tree and liver (see below and Fig. 24.46).

**Computed tomography and magnetic resonance imaging**

Computed tomography (CT) detects smaller focal lesions in the liver, especially when combined with contrast injection (Fig. 24.9). Magnetic resonance imaging (MRI) can also be used to localise and confirm the aetiology of focal liver lesions, particularly primary and secondary tumours.

Hepatic angiography is seldom used nowadays as a diagnostic tool, since CT and MRI are both able to provide images of hepatic vasculature, but it still has a therapeutic role in the embolisation of vascular tumours, such as hepatocellular carcinoma. Hepatic venography is now rarely performed.

**Cholangiography**

Cholangiography can be undertaken by magnetic resonance cholangiopancreatography (MRCP; Fig. 24.10), endoscopy (endoscopic retrograde cholangiopancreatography, ERCP) or the percutaneous approach (percutaneous transhepatic cholangiography, PTC). The latter does not allow the ampulla of Vater or pancreatic duct to be visualised. Endoscopic ultrasound can also provide high-quality biliary imaging safety (see below), MRCP is as good as ERCP at providing images of the biliary tree but is safer, and there is now little, if any, role for diagnostic ERCP. Both endoscopic and percutaneous approaches allow therapeutic interventions, such as the insertion of biliary stents across bile duct strictures. The percutaneous approach is used only if it is not possible to access the bile duct endoscopically.

**Endoscopic ultrasound**

Endoscopic ultrasound (EUS) is complementary to MRCP in the diagnostic evaluation of the extrahepatic biliary tree, ampulla of Vater and pancreas. With the ultrasonic probe in the duodenum, high-quality images are obtained, tissue sampling can be performed and, increasingly, therapeutic drainage of biliary obstruction can be performed. EUS has the advantage over ERCP of not exposing patients to the risk of pancreatitis, among other complications of bile duct cannulation.

**Non-invasive markers of hepatic fibrosis**

Fibrosis is a key predictor of prognosis in chronic liver disease, and can help to guide monitoring and treatment decisions. This is now largely assessed by non-invasive markers of liver fibrosis. A number of indirect fibrosis markers have been described, including bilirubin, AST/ALT ratio and platelet count. Simple scoring systems such as the FIB-4 score and NAFLD fibrosis score combine routinely available blood tests and clinical risk factors, and are often used as screening tests for fibrosis risk. These tests have a high negative predictive value, with a normal value making advanced fibrosis very unlikely, but a relatively low positive predictive value. Whilst these have been validated across a range of aetiologies, the cut-off values used (e.g. for FIB-4) may differ according to aetiology, and serum-based tests are less reliable in alcohol-related liver disease.

Fibrosis can also be assessed using more specific serum tests. FibroTest® combines five serum markers including \( \alpha_2 \)-macroglobulin, haptoglobin and apolipoprotein A1. The Enhanced Liver Fibrosis (ELF®) serological assay provides direct assessment of fibrogenesis and fibrosis using a combination of hyaluronic acid, procollagen peptide III (PIINP) and tissue inhibitor of metalloproteinase 1 (TIMP1).

An alternative to serological markers is transient elastography (Fibroscan®), in which ultrasound-based shock waves are sent through the liver to measure stiffness as a surrogate for hepatic fibrosis. This is quick, non-invasive and provides immediate results. Depending on the threshold used, this can exclude significant fibrosis or diagnose cirrhosis. However, results can be influenced by the presence of severe inflammation and become less reliable with increasing obesity. Magnetic resonance elastography appears more reliable and is not influenced by obesity, but is costly and not widely available.

**Histological examination**

A liver biopsy can confirm the severity of liver damage and provide aetiological information. It is performed percutaneously with a Trucut or Menghini needle, usually through an intercostal space under local anaesthesia, or radiologically using a transjugular approach.

Percutaneous liver biopsy is a relatively safe procedure if the conditions detailed in Box 24.6 are met, but carries a mortality of about 0.01%. The main complications are abdominal and/or shoulder pain, bleeding and biliary peritonitis. Liver biopsies can be carried out in patients with defective haemostasis if:

- the defect is corrected with fresh frozen plasma and platelet transfusion,
- the biopsy is obtained by the transjugular route, or

---

**Fig. 24.9** Computed tomography in a patient with cirrhosis. The liver is small and has an irregular outline (black arrow), the spleen is enlarged (long white arrow), fluid (ascites) is seen around the liver, and collateral vessels are present around the proximal stomach (short white arrow).

**Fig. 24.10** Magnetic resonance cholangiopancreatography showing a biliary stricture due to cholangiocarcinoma in the distal common bile duct (arrow). The proximal common bile duct (CBD) is dilated but the pancreatic duct (PD) is normal.
24.6 Conditions required for safe percutaneous liver biopsy

- Cooperative patient
- It is recommended that for non-lesional liver biopsy in patients with chronic liver disease a transvenous route should be used if INR > 1.4
- For percutaneous lesional biopsies the INR should be < 2
- Platelet count > 50 x 10^9/L
- Exclusion of bile duct obstruction, localised skin infection, advanced chronic obstructive pulmonary disease, marked ascites and severe anaemia
- Liver biopsy should be avoided in unstable patients with uncontrolled bleeding, bacterial infection and significant renal impairment.

(INR = International Normalised Ratio)

- the procedure is conducted percutaneously under ultrasound control and the needle track is then plugged with procoagulant material.

In patients with potentially resectable malignancy, biopsy should be avoided due to the potential risk of tumour dissemination (biopsy track seeding). Operative or laparoscopic liver biopsy may sometimes be valuable.

Liver biopsy is used where there is uncertainty as to the cause of liver disease, or to quantify the degree of inflammation (‘grade’) or fibrosis (‘stage’). Semi-quantitative scoring systems may be used to describe the degree of inflammation or fibrosis. Although often regarded as the ‘gold standard’ investigation for liver disease, liver biopsies are limited by sampling error, with studies showing significant variation in both grade and stage between simultaneous paired biopsies. The use of special histological stains can help in determining aetiology. The clinical features and prognosis of these changes are dependent on the underlying aetiology and are discussed in the relevant sections below.

Presenting problems in liver disease

Liver injury may be either acute or chronic. The main causes are listed in Fig. 24.11 and discussed in detail later in the chapter. In the UK, liver disease is the only one of the top causes of mortality that is steadily increasing (Fig. 24.12). Mortality rates have risen substantially over the last 30 years, with a near-fivefold increase in liver-related mortality in people younger than 65 years. The rate of increase is substantially higher in the UK than in other countries in Western Europe.

- Acute liver injury may present with non-specific symptoms of fatigue and abnormal LFTs, or with jaundice and acute liver failure.
- Chronic liver injury is defined as hepatic injury, inflammation and/or fibrosis occurring in the liver for more than 6 months. In the early stages, patients can be asymptomatic with fluctuating abnormal LFTs. With more severe liver damage, however, the presentation can be with jaundice, portal hypertension or other signs of cirrhosis and hepatic decompensation (Box 24.7). Patients with clinically silent chronic liver disease frequently present when abnormalities in liver function are observed on routine blood testing, or when clinical events, such as an intercurrent infection or surgical intervention, cause the liver to decompensate. Patients with compensated cirrhosis can undergo most forms of surgery without significantly increased risk. Surgical complications are more common in patients with decompensated cirrhosis and the presence of portal hypertension with intra-abdominal varices can make abdominal surgery more hazardous. The possibility of undiagnosed liver disease should be borne

![Fig. 24.11 Causes of acute and chronic liver injury. *Although there is often evidence of chronic liver disease at presentation, may present acutely with jaundice. In alcoholic liver disease this is due to superimposed alcoholic hepatitis. (NAFLD = non-alcoholic fatty liver disease; PBC = primary biliary cholangitis; PSC = primary sclerosing cholangitis)](image)

in mind in all patients in at-risk groups undergoing significant surgery. Many liver disorders are more common in older age and can pursue a more aggressive course (Box 24.8).

**Abnormal liver function tests**

LFTs are frequently requested in patients who have no symptoms or signs of liver disease, as part of routine health checks, insurance medicals or drug monitoring. The prevalence of abnormal LFTs has been reported to be as high as 10%–20% in some studies. In the majority of cases, these will not reflect significant underlying liver disease. However, many patients with chronic liver disease are asymptomatic or have vague, non-specific symptoms. The most common abnormalities are alcohol-related or non-alcoholic fatty liver disease. Since effective medical treatments are now available for many types of chronic liver disease, further evaluation is usually warranted to make sure the patient does not have a treatable condition. Biochemical abnormalities in chronic liver disease often fluctuate over time; even mild abnormalities can therefore indicate significant underlying disease and so warrant follow-up and investigation.

When abnormal LFTs are detected, a thorough history should be compiled to determine the patient’s alcohol consumption, drug use (prescribed, over-the-counter or recreational), risk factors for viral hepatitis (e.g. blood transfusion, injection drug use, tattoos), the presence of autoimmune diseases, family history, neurological symptoms and the presence of features of the metabolic syndrome, including diabetes and/or obesity (see Box 24.5 and Fig. 22.6). Stigmata of chronic liver disease should be looked for but further investigations are indicated even in the absence of these signs.

Both the pattern of enzyme abnormality (hepatitic or cholestatic) and the degree of elevation are helpful in determining the cause of underlying liver disease (Boxes 24.9 and 24.10). The investigations that make up a standard liver screen and additional or confirmatory tests are shown in Boxes 24.4 and 24.5. An algorithm for investigating abnormal LFTs is provided in Fig. 24.13.

**Jaundice**

Jaundice is usually detectable clinically when the plasma bilirubin exceeds 40µmol/L (~2.5mg/dL). The causes of jaundice overlap with the causes of abnormal LFTs discussed above. In a patient with jaundice it is useful to consider whether the cause might be pre-hepatic, hepatic or post-hepatic, and there are often important clues in the history (Box 24.11).

### Pre-hepatic jaundice

This is caused either by haemolysis or by congenital hyperbilirubinaemia, and is characterised by an isolated raised bilirubin level.

In haemolysis, destruction of red blood cells or their marrow precursors causes increased bilirubin production. Jaundice due to haemolysis is usually mild because a healthy liver can excrete a bilirubin load six-times greater than normal before unconjugated bilirubin accumulates in the plasma. This does not apply to newborns, who have less capacity to metabolise bilirubin.

The most common form of non-haemolytic hyperbilirubinaemia is Gilbert syndrome, an inherited disorder of bilirubin metabolism (Box 24.12). Other inherited disorders of bilirubin metabolism are very rare.

### Hepatic jaundice

This is characterised by jaundice due to hepatic dysfunction (usually indicated by abnormal liver enzymes) but normal biliary imaging. This can be due to acute hepatocellular injury (see Box 24.9), intrahepatic cholestasis (see Box 24.10) or decompensation of cirrhosis. ‘Hepatic’ jaundice can be a manifestation of extrahepatic disease such as sepsis or right heart failure. In all of these, jaundice results from an inability of the liver to transport bilirubin into the bile, occurring at any point between uptake of unconjugated bilirubin into the cells and transport of conjugated bilirubin into the canalicul. In addition, swelling of cells and oedema resulting...
**Clinical situation**

**Isolated raised bilirubin**
- Recheck with conjugated (direct) bilirubin
- Exclude haemolysis

**Cholestatic liver enzymes** *(Raised ALP)*
- Check GGT
  - Elevated GGT/elevated ALP: Full history/examination
  - Liver US (exclude focal lesion)
  - Aetiology screen with autoantibodies, immunoglobulins, ferritin and transferrin saturation (Box 24.4)

**Raised GGT only**
- Full history and examination

**Hepatitic liver enzymes** *(Raised ALT or AST)*
- Full history/examination
- Liver US
- Aetiology screen including hepatitis B and C, autoantibodies, immunoglobulins, caeruloplasmin, α1-antitrypsin, ferritin and transferrin saturation (Box 24.4)

**Ad/Management**

- Reassure, as likely Gilbert syndrome
- Liver disease unlikely: exclude alternative cause of raised ALP, e.g. bone disease
- Bile ducts dilated: Consider MRCP/EUS
- Bile ducts non-dilated: Consider liver biopsy
- Treat underlying disorder
- NAFLD/increased BMI: stage disease; lifestyle modification (diet and exercise)
- Alcohol: stage disease; reduce alcohol to safe limits/consider abstinence
- Enzyme induction from medication; review current medication
- NAFLD: stage disease; lifestyle modification (diet and exercise)
- Alcohol: stage disease; reduce alcohol to safe limits/consider abstinence
- Specialist referral to treat underlying disease depending on test results and consider liver biopsy

---

**24.11 Key history points in patients with jaundice**

**Symptoms***
- Itch
- Abdominal pain (suggests gallstones)
- Weight loss (chronic liver disease and malignancy)
- Dark urine and pale stools
- Fever ± rigors
- Dry eyes/dry mouth

**Recent drug history**
**Other**
- Alcohol history
- Exposure to intravenous drugs or blood transfusions
- Travel history and country of birth
- Metabolic syndrome (increased body mass index ± type 2 diabetes/hypertension)
- Autoimmune disease history
- Inflammatory bowel disease
- Family history of liver disease, autoimmune disease or the metabolic syndrome

*Symptoms may be absent and abnormal liver function tests detected incidentally.

---

**Post-hepatic jaundice**

Post-hepatic jaundice may be caused by obstruction of the larger bile ducts, usually between the hilum and the ampulla of Vater, resulting in biliary dilatation on imaging.

The causes of post-hepatic jaundice are listed in Box 24.10. Post-hepatic jaundice is most commonly due to diseases affecting the

---

**Fig. 24.13 Suggested management of abnormal liver function tests in asymptomatic patients.** (ALP = alkaline phosphatase; ASP = aspartate aminotransferase; BMI = body mass index; EUS = endoscopic ultrasound; GGT = γ-glutamyl transferase; MRCP = magnetic resonance cholangiopancreatography; NAFLD = non-alcoholic fatty liver disease; US = ultrasound)
extrahepatic bile ducts, which are often amenable to surgical or endoscopic correction.

Clinical features (Box 24.13) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 24.14). Post-hepatic jaundice is characteristically associated with pale stools, dark urine and itch, although these features also occur with intrahepatic cholestasis. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically inflamed, stone-containing gallbladder cannot readily dilate. This is Courville's Law, and suggests that jaundice is due to a malignant biliary obstruction (e.g. pancreatic cancer). Cholangitis is characterised by 'Charcot's triad' of jaundice, right upper quadrant pain and fever.

Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than ALT, although a high ALT is often seen with ductal gallstones presumably due to a cholangitic element. Ultrasound is usually the first-line imaging to determine whether there is dilatation of the biliary tree (Fig. 24.14). MRCP provides a more detailed assessment of the biliary tree, especially where ductal stones are suspected, whereas CT is preferred for assessing malignant lesions. EUS provides an additional modality for investigation of lower common bile duct obstruction.

Management of post-hepatic jaundice depends on the underlying cause and is discussed in the relevant sections below.

### 24.13 Clinical features and complications of cholestatic jaundice

**Cholestasis**

**Early features**
- Jaundice
- Dark urine

**Late features**
- Malabsorption (vitamins A, D, E and K): weight loss, steatorrhoea, osteomalacia, bleeding tendency
- Xanthelasma and xanthomas

**Cholangitis**
- Fever
- Rigors
- Pain (if gallstones present)

**24.14 Clinical features suggesting an underlying cause of cholestatic jaundice**

*Each of these diseases can give rise to almost any of the clinical features shown but the box indicates the most likely cause of the clinical features listed.*

### Acute liver failure

Acute liver failure is a rare but life-threatening condition characterised by a rapid progressive deterioration in liver function. A variety of insults can lead to marked elevation of transaminases, or acute liver injury. This is considered severe if it results in jaundice and coagulopathy. A small number of such patients will go on to develop encephalopathy, which is the cardinal feature of acute liver failure. The absence of evidence of
pre-existing liver disease distinguishes it from encephalopathy due to decompensated cirrhosis or acute-on-chronic liver failure. It is critical, therefore, to understand whether liver failure is a truly acute event or an acute deterioration on a background of pre-existing injury (which may itself not have been diagnosed). Although liver biopsy may ultimately be necessary, it is the presence or absence of the clinical features suggesting chronicity that guides the clinician.

Acute liver failure may be subclassified into hyperacute, acute and subacute, according to the interval between onset of jaundice and encephalopathy (Box 24.15). This can help to identify likely cause and predict prognosis. Patients with subacute liver failure are more likely to be drug-induced or of indeterminate cause, and to have a worse outcome with medical care alone than those with a hyperacute course.

Pathophysiology

Any cause of hepatocyte damage can produce acute liver failure, provided it is sufficiently severe (Fig. 24.15). Acute viral hepatitis is the most common cause worldwide, whereas paracetamol toxicity is the most frequent cause in the UK. Acute liver failure occurs occasionally with other drugs (prescription, recreational or herbal), or from Amanita phalloides (mushroom) poisoning, in autoimmune hepatitis, in acute fatty liver of pregnancy, in Wilson’s disease, following shock and, rarely, in extensive malignant disease of the liver. In 10% of cases, the cause of acute liver failure remains unknown and these patients are often labelled as having ‘non-A–E viral hepatitis’ or ‘cryptogenic’ acute liver failure.

Clinical assessment

Cerebral disturbance (hepatic encephalopathy and/or cerebral oedema) is the cardinal manifestation of acute liver failure. The initial clinical features are often subtle and include reduced alertness and poor concentration, progressing through behavioural abnormalities, such as restlessness and aggressive outbursts, to drowsiness and coma (Box 24.16). Cerebral oedema may occur due to increased intracranial pressure, causing unequal or abnormally reacting pupils, fixed pupils, hypertensive episodes, bradycardia, hyperventilation, profuse sweating, local or general myoclonus, focal fits or decerebrate posturing. Papilloedema occurs rarely and is a late sign.

More general symptoms include weakness, nausea and vomiting. The patient may be jaundiced but jaundice may not be present at the outset (e.g. in paracetamol overdose), and there are a number of exceptions, including Reye syndrome, in which jaundice is rare. Occasionally, death may occur in hyperacute liver failure before jaundice develops. Feter hepaticus can be present. The liver is usually of normal size but later

Fig. 24.14 Investigation of jaundice. (CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; LDH = lactate dehydrogenase; LFTs = liver function tests; MRCP = magnetic resonance cholangiopancreatography)
Fig. 24.15 Causes of acute liver failure in the UK. The relative frequency of the different causes varies according to geographical area.

becomes smaller. Hepatomegaly is unusual and, in the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd–Chiari syndrome, p. 909). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy.

**Investigations**

The patient should be investigated to determine the cause of the liver failure and the prognosis (Boxes 24.17 and 24.18). Hepatitis B core IgM antibody is the best screening test for acute hepatitis B infection, as liver damage is due to the immunological response to the virus, which has often been eliminated, and the test for hepatitis B surface antigen (HBsAg) may be negative by the time liver failure develops. The PT rapidly becomes prolonged as coagulation factor synthesis fails; this is the laboratory test of greatest prognostic value and should be carried out at least twice daily. Vitamin K should be given to ensure that the PT is not prolonged as a result of underlying vitamin K deficiency, but fresh frozen plasma should be avoided except in major bleeding as it will interfere with the use of PT for monitoring. Factor V levels can be used instead of the PT to assess the degree of liver impairment. Plasma bilirubin also predicts outcome in non-paracetamol causes of acute liver failure. Plasma aminotransferase activity is particularly high after paracetamol overdose, reaching 100–500 times normal, but falls as liver damage progresses and is not helpful in determining prognosis. Plasma albumin remains normal unless the course is prolonged. Percutaneous liver biopsy is contraindicated because of the severe coagulopathy, but biopsy can be undertaken using the transjugular route if appropriate.

**24.17 Investigations to determine the cause of acute liver failure**

- Toxicology screen of blood and urine
- HBsAg, IgM anti-HBc
- IgM anti-HAV
- Anti-HEV, HCV, cytomegalovirus, herpes simplex, Epstein–Barr virus
- Caeruloplasmin, serum copper, urinary copper, slit-lamp eye examination
- Autoantibodies: ANA, ASMA, LKM, SLA
- Immunoglobulins
- Ultrasound of liver and Doppler of hepatic veins

(ANA = antinuclear antibody; anti-HBc = antibody to hepatitis B core antigen; ASMA = anti-smooth muscle antibody; HAV = hepatitis A virus; HBsAg = hepatitis B surface antigen; HCV = hepatitis C virus; HEV = hepatitis E virus; IgM = immunoglobulin M; LKM = liver–kidney microsomal antibody; SLA = soluble liver antigen)

**24.18 Adverse prognostic criteria in acute liver failure**

**Paracetamol overdose**

- pH < 7.25 at or beyond 24 hours following the overdose and after fluid resuscitation
- Prothrombin time > 100 secs plus encephalopathy grade 3 or 4 plus serum creatinine > 300 μmol/L (≥ 3.38 mg/dL) or anuria
- Arterial lactate > 5 mmol/L at presentation and > 4 mmol/L 24 hours later after fluid resuscitation

**Non-paracetamol cases**

- Prothrombin time > 100 secs (or INR > 6.5) with any grade of encephalopathy
- Any three of the following:
  - Jaundice to encephalopathy time > 7 days
  - Age < 10 or > 40 years
  - Bilirubin > 300 μmol/L (≥ 17.6 mg/dL)
  - Prothrombin time > 50 secs (or INR > 3.5)
- Unfavourable aetiology, e.g. seronegative hepatitis or idiosyncratic drug reaction

1Predict a mortality rate of > 90% and are an indication for possible liver transplantation. 2In the absence of encephalopathy INR > 2 after vitamin K repletion is mandatory. (INR = International Normalised Ratio)
Management

Patients with acute liver failure should be treated in a high-dependency or intensive care unit as soon as progressive prolongation of the PT occurs or hepatic encephalopathy is identified (Box 24.19), so that prompt treatment of complications can be initiated (Box 24.20). Conservative treatment aims to support other organ systems in the hope that hepatic regeneration will occur. N-acetylcysteine therapy should be given early to all patients in whom paracetamol toxicity is suspected, although the benefits are less clear in non-paracetamol-induced acute liver failure. Liver transplantation is an increasingly important treatment option for acute liver failure, and criteria have been developed to identify patients unlikely to survive without a transplant (see Box 24.19). Patients should, wherever possible, be transferred to a transplant centre before these criteria are met to allow time for assessment and to maximise the time for a donor liver to become available. Survival following liver transplantation for acute liver failure is improving and 1-year survival rates of 80%–90% can be expected. A number of artificial liver support systems have been developed and evaluated for use as a bridge to either transplantation or recovery. None, however, has entered routine clinical use.

Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour (Box 24.21). The most common liver tumours in Western countries are liver metastases, whereas primary liver cancer complicating chronic viral hepatitis is more common in the Far East. Unlike carcinoma metastases, those from neuro-endocrine tumours typically cause massive hepatomegaly but without significant weight loss. Cirrhosis can be associated with either hepatomegaly or reduced liver size in advanced disease.

Ascites

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (>1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill/liquid wave. Other features include eversion of the umbilicus, herniae, abdominal striate, divarication of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

Pathophysiology

The most common causes of ascites are cirrhosis, intra-abdominal malignancy and heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease (Box 24.22). Splanchnic arterial vasodilatation is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic

- Sinusoidal obstruction syndrome (Veno-occlusive disease)
- Protein-losing enteropathy
- Severe malnutrition

**Rare causes**

- Hyperthyroidism
- Meigs syndrome

**High SAAG**

- Cardiac failure
- Constrictive pericarditis

---

*1 Early Budd–Chiari syndrome presents with ascites with high protein content (>25 g/L) and elevated SAAG. In chronic Budd–Chiari syndrome the protein concentration may fall but SAAG remains elevated.
*2 Meigs syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour. Although usually reported as being associated with a low SAAG, it can also be seen with a high SAAG. (SAAG = serum–ascites albumin gradient; see text)
vasodilation as cirrhosis advances. This leads to activation of the renin–angiotensin system with secondary aldosterone, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity of the kallikrein–kinin system (Fig. 24.16). These systems tend to normalise arterial pressure initially but produce salt and water retention. In this setting, the combination of splanchnic arterial vasodilatation and portal hypertension alters intestinal capillary permeability, promoting accumulation of fluid within the peritoneum.

**Investigations**

Ultrasoundography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can be used to obtain ascitic fluid for analysis. The appearance of ascitic fluid may point to the underlying cause (Box 24.23). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and identified only on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the protein concentration and the serum–ascites albumin gradient (SAAG) can be a useful tool to distinguish ascites of different aetiologies. Cirrhotic patients typically develop ascites with a low protein concentration (‘transudate’; protein concentration <25 g/L [2.5 g/dL]) and relatively few cells. In up to 30% of patients, however, the total protein concentration is >30 g/L (3.0 g/dL). In these cases, it is useful to calculate the SAAG by subtracting the concentration of the ascites fluid albumin from the serum albumin. A gradient of >11 g/L (1.1 g/dL) is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a SAAG of >11 g/L (1.1 g/dL) but, unlike in cirrhosis, the total protein content is usually >25 g/L (2.5 g/dL). Conversely, conditions including nephrotic syndrome, protein-losing enteropathy and severe malnutrition result in ascites with low protein concentration and a SAAG of <11 g/L (1.1 g/dL) due to diminished serum oncotic pressure.

High protein ascites (‘exudate’; protein concentration >25 g/L [2.5 g/dL] or a SAAG of <11 g/L (1.1 g/dL) raises the possibility of infection (especially tuberculosis), malignancy, pancreatic ascites or, rarely, hypothyroidism. Ascitic amylase activity of >1000 U/L identifies pancreatic ascites, whereas low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells but has a low sensitivity unless large volumes are sent. Polymorphonuclear leucocyte counts of >250x10⁹/L strongly suggest infection (spontaneous bacterial peritonitis; see below). Laparoscopy can be invaluable in detecting peritoneal disease.

The presence of triglyceride at a level >1.1 g/L (110 mg/dL) is diagnostic of chylous ascites and suggests anatomical or functional abnormality of lymphatic drainage from the abdomen. Chylous ascites has a characteristic milky-white appearance.

**Management**

Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid/electrolyte balance, and precipitate hepatic encephalopathy (see below). Treatment of transudative ascites is based on restricting sodium intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy is treated with paracentesis but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid (or 1 kg body weight) daily to avoid excessive fluid depletion.

**Sodium restriction**

Restriction of dietary sodium intake is essential to achieve negative sodium balance and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/24 hrs (‘no added salt diet’) is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 24.24). Restriction of water intake to 1.0–1.5 L/24 hrs is rarely needed unless the plasma sodium falls below 125 mmol/L.

**Diuretics**

Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the first-line drug because it is a powerful aldosterone antagonist; it can, however, cause painful gynaecomastia and hyperkalaemia, in which case amiloride (5–10 mg/day) can be substituted. This is often combined with a loop diuretic, such as furosemide (40–160 mg/day). Patients must be monitored for electrolyte imbalance and renal dysfunction. Diuresis may be improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to maximal doses of

spironolactone and furosemide (diuretic-resistant), or who are unable to tolerate these doses due to hyponatraemia or renal impairment (diuretic-intolerant), are considered to have refractory ascites and should be treated by other measures.

Paracentesis

First-line treatment of refractory ascites is large-volume paracentesis. Paracentesis to dryness is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% or 25% human albumin solution (HAS) for every 2–3 L of ascites drained). Paracentesis can be used as an initial therapy or when other treatments fail. Drains should be removed after 6–12 hours to reduce risk of infection.

Transjugular intrahepatic portosystemic shunt

A transjugular intrahepatic portosystemic shunt (TIPSS; p. 883) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. TIPSS can be used in patients awaiting liver transplantation or in those with reasonable liver function, but can aggravate encephalopathy in those with poor function.

Complications

Renal failure

Renal dysfunction is commonly seen in patients with liver cirrhosis, related to pre-renal, intrinsic and post-renal causes. It is most frequently related to dehydration, diuretic therapy and/or sepsis. However, patients with cirrhosis and ascites may develop a distinct type of renal dysfunction termed hepatorenal syndrome (HRS).

Hepatorenal syndrome

HRS is renal dysfunction that occurs due to reduced renal perfusion, resulting from both haemodynamic alterations in the arterial circulation (splanchnic vasodilatation/renal vasoconstriction) and overactivity of endogenous vasoactive systems. HRS has traditionally been classified into two subtypes but the terminology has recently changed to reflect changes in the understanding and definition of both acute kidney injury (AKI) and chronic kidney disease (CKD).

Type 1 HRS (now termed HRS-AKI) involves a rapid reduction in renal function (AKI) that is usually precipitated by an acute event, including bacterial infection, GI haemorrhage, alcoholic hepatitis or acute liver failure, which disturbs the abnormal renal haemodynamics and has a poor prognosis.

Traditionally HRS was diagnosed with a serum creatinine cutoff of >1.5 mg/dL (>133 μmol/L) but this has been modified to use a change in renal function from baseline and removing the cutoff threshold. This was necessary to avoid delay in diagnosis and initiation of treatment for HRS. The diagnostic criteria from HRS AKI are shown in Box 24.25.

Type II HRS (now termed HRS non-acute kidney injury or HRS-NAKI) is a stable or slowly progressive form of renal dysfunction developing over weeks to months, in the absence of an obvious precipitant. It is characterised clinically by diuretic-resistant ascites.

Management of HRS-AKI involves identifying and treating precipitating factors. Diuretics and beta-blockers should be discontinued. Nephrotoxic drugs including vasodilators and non-stereoidal anti-inflammatories should be stopped. Infections should be sought and treated. Volume replacement should be used to treat fluid loss/deficits. Intravenous albumin infusions in combination with terlipressin (1–2 mg every 4–6 hours) have been shown to improve short-term survival. In countries where terlipressin is not available, a combination of midodrine, octreotide and albumin may be used. TIPSS may be effective for treatment of HRS in highly selected patients. Haemodialysis may be considered in patients who fail to respond to treatment as either a bridge to transplant (in suitable patients) or as a bridge to recovery in patients with a reversible liver injury (typically acute liver failure).

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) is the most common bacterial infection in patients with cirrhosis, and results from translocation of bacteria from the intestine into ascites. It may present with abdominal pain or fever in a patient with obvious features of cirrhosis and ascites. However, abdominal signs are mild or absent in about one-third of patients, and it may present with hepatic encephalopathy or a non-specific deterioration. SBP is associated with a high rate of acute kidney injury and mortality, and prompt recognition is critical. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count of >250 x 10³/L almost invariably indicates infection. Most organisms isolated are of enteric origin and Escherichia coli is the most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime or piperacillin/tazobactam. Patients with jaundice and renal impairment also benefit from intravenous albumin (1.5 g/kg on day 1 and 1.0 g/kg on day 3). Recurrence of SBP is common, but is reduced by prophylactic antibiotics such as norfloxacin (400 mg/day), ciprofloxacin (750 mg/week) or cotrimoxazole (960 mg/day). Primary antibiotic prophylaxis also reduces the incidence of SBP in patients with low ascitic protein <15 g/L.

Prognosis

Only 10%–20% of patients survive for 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.
Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by liver disease that occurs in 30%–40% of patients with cirrhosis. It causes a spectrum of symptoms ranging from mild fluctuating cognitive impairment to coma. The degree of encephalopathy can be graded from 1 to 4, and this is useful in assessing progression or response to therapy (see Box 24.10). The earliest features are very mild and easily overlooked, but as the condition becomes more severe, inability to concentrate, delirium, disorientation, drowsiness, slurring of speech and eventually coma develop. Seizures are rare. Examination usually shows a flapping tremor (asterixis), inability to perform simple mental arithmetic tasks or to draw objects such as a star (constructional apraxia, p. 861) and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs; if these are present, other causes must be sought. Fetor hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

Many conditions can cause similar presentations to encephalopathy. Simple delirium needs to be differentiated from infection, alcohol withdrawal and Wernicke’s encephalopathy, and coma from subdural haematoma, which can occur after a fall, especially in alcohol misuse (Box 24.26). When an episode develops acutely, a precipitating factor may be found (Box 24.27).

Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating gut-derived neurotoxins that are normally metabolised by the liver and excluded from the systemic circulation. Affected patients usually have evidence of both liver failure and portosystemic shunting of blood, but the balance between these varies between individuals. Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. The “neurotoxins” causing encephalopathy are unknown but are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. Ammonia has traditionally been considered an important factor, but the correlation between serum ammonia levels and encephalopathy is poor. Recent interest has focused on γ-aminobutyric acid (GABA) as a mediator, along with octopamine, amino acids, mercaptans and fatty acids that can act as neurotransmitters. The brain in cirrhosis may also be sensitised to other factors, such as drugs that can precipitate hepatic encephalopathy (see Box 24.27). Disruption of the function of the blood–brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

Investigations

The diagnosis can usually be made clinically; when doubt exists, an electroencephalogram shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. Increased concentrations can, however, occur in the absence of clinical encephalopathy, rendering this investigation of little diagnostic value.

Management

The principles are to treat or remove precipitating causes (Box 24.27) and to suppress the production of neurotoxins by bacteria in the bowel. Lactulose (15–30 mL 3 times daily) is increased gradually until the bowels are moving twice daily. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Phosphate enemas may be required in patients where the oral route is compromised or in patients with refractory constipation. Rifaximin (550 mg twice daily) is a well-tolerated, non-absorbed antibiotic that acts by reducing the bacterial content of the bowel and is effective in reducing episodes of recurrent hepatic encephalopathy. There is some evidence to support the amino acid combination l-ornithine l-arginine (LOLA) in lowering ammonia levels and improving encephalopathy. In cases of reduced conscious level, endotracheal intubation may be required for airway protection. Dietary protein restriction is no longer recommended because it can
lead to a worsening nutritional state in already malnourished patients. Chronic or refractory encephalopathy is one of the main indications for liver transplantation.

### Variceal bleeding

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices (Fig. 24.17) is common in chronic liver disease. Investigation and management are discussed on page 797 and the specific management of variceal bleeding on page 882.

### Cirrhosis

Cirrhosis is characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. It is the most common cause of portal hypertension. Worldwide, the most common causes are chronic viral hepatitis, prolonged excessive alcohol consumption and NAFLD, but any condition leading to persistent or recurrent hepatocyte injury may lead to cirrhosis. The causes of cirrhosis are listed in Box 24.28.

Cirrhosis may also occur in prolonged biliary injury, as is found in primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC) and post-surgical biliary strictures. Persistent impairment of venous return from the liver, such as is found in sinusoidal obstruction syndrome (SOS; veno-occlusive disease), Budd–Chiari syndrome and cardiac hepatopathy, can also result in cirrhosis.

### Pathophysiology

Following liver injury, stellate cells in the space of Disse (see Fig. 24.3) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and other mediators that promote hepatocyte damage and tissue fibrosis (see Fig. 24.4).

Cirrhosis is technically a histological diagnosis (Fig. 24.18), although most cases will be diagnosed on a combination of imaging, clinical signs and fibrosis markers. Fibrosis evolves over years, and the progression can be described semi-quantitatively (Fig. 24.19). Fibrosis and widespread hepatocyte loss lead to distortion of the normal liver architecture that disrupts the hepatic vasculature, causing portosystemic shunts. These changes usually affect the whole liver, but in biliary cirrhosis (e.g. PBC) they can be patchy.

### Clinical features

The clinical presentation is highly variable. Some patients are asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly, signs of portal hypertension or hepatic insufficiency. When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea and upper abdominal discomfort (Box 24.29). Cirrhosis will occasionally present because of shortness of breath due to a large right pleural effusion, or with hepatopulmonary syndrome (p. 909).

**Fig. 24.18 Histological features in normal liver, hepatic fibrosis and cirrhosis.**

[A] Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intralobular bile duct branch of the hepatic artery and portal venous radical. [B] Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular) and linking adjacent portal tracts and hepatic veins. [C] A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).

Hepatomegaly is common when the cirrhosis is due to alcoholic liver disease or haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. The liver is often hard, irregular and non-tender. Jaundice is mild when it first appears and is due primarily to a failure to excrete bilirubin. Palmar erythema (redness over the thenar and hypothenar eminences) can be seen early in the disease but is of limited diagnostic value, as it occurs in many other conditions associated with a hyper-dynamic circulation, including pregnancy, as well as being found in some healthy people. Spider telangiectasias (or spider naevi) occur and comprise a central arteriole (that occasionally raises the skin surface), from which small vessels radiate. They blanch with pressure and refill from the centre outwards, are usually found on the hands, face and upper chest. One or two small spider telangiectasias may be present in up to 15% of young healthy adults and may occur transiently in greater numbers in the third trimester of pregnancy, but otherwise multiple spider telangiectasias are a strong
indicator of liver disease. Florid spider telangiectasia and gynaecomastia are most common in alcohol-related cirrhosis, possibly related to phyto-oestrogens in alcoholic drinks. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Clubbing of the fingers and toes is not a sign of cirrhosis but is seen in combination with hypoxia in hepatopulmonary syndrome.

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances.

Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below). Jaundice, ascites, encephalopathy and variceal bleeding signify advanced disease, and are associated with a worse prognosis. The term ‘hepatic decompensation’ or ‘decompensated liver disease’ is often used when any of these are present.

Other clinical and laboratory features may be present (Box 24.30); these include peripheral oedema, renal failure, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis.

Anaemia is common and often multifactorial, due to a combination of chronic inflammation, bone marrow suppression, haemolysis or chronic blood loss.

**Management**

This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications, including ascites, hepatic encephalopathy, portal hypertension and varices.

**Nutrition in cirrhosis**

Malnutrition is a frequent complication, affecting up to 50% of patients with decompensated cirrhosis. Loss of muscle mass (sarcopenia) is associated with a higher rate of complications including infections, encephalopathy and ascites. Although BMI is the most widely used measure of nutritional status, sarcopenia can coexist with obesity especially in patients with NASH. Handgrip strength is a simple and inexpensive way to assess muscle function, and predicts morbidity and mortality in cirrhosis. Daily calorie intake should be no lower than 35 kcal/kg body weight with a daily protein intake of 1.2–1.5 g/kg. A late evening snack will help to minimise overnight fasting which could otherwise trigger a catabolic state in cirrhosis. If patients are unable to achieve adequate oral intake, enteral feeding should be considered.

**Screening for complications**

Once the diagnosis of cirrhosis is made, endoscopy should be considered to screen for oesophageal varices. As cirrhosis is associated with an increased risk of hepatocellular carcinoma, patients should be placed under regular surveillance for it. Cirrhosis is associated with an increased risk of osteoporosis and associated fractures, and bone mineral density measurement is recommended.

Chronic liver failure due to cirrhosis can also be treated by liver transplantation. This currently accounts for about three-quarters of all liver transplants.

**Prognosis**

Most chronic liver diseases run a gradually progressive course, although many patients present with advanced disease and/or serious complications that carry a high mortality. Prognosis is more favourable when the underlying cause can be corrected. Cirrhosis can be categorised into two prognostic groups: compensated and decompensated. Decompensated cirrhosis is defined by the presence of complications, including ascites, variceal bleeding, jaundice and encephalopathy, which are the main determinants of patient survival. Compensated patients have a relatively good prognosis with median survival >12 years. However, in decompensated cirrhosis median survival is around 2 years, albeit with significant patient-to-patient variability.

Raised bilirubin, low albumin and prolonged PT reflect impaired liver function. Along with renal dysfunction and hyponatraemia, these are all bad prognostic features (Box 24.31 and Fig. 24.20). Prognostic scores including Child–Pugh and MELD (Model for End-stage Liver Disease) scores can be used to assess prognosis in chronic liver disease. MELD is a complex algorithm including serum creatinine, serum bilirubin and INR (Box 24.32). The MELD-Na score incorporates serum sodium into this calculation and provides better prognostic accuracy in predicting mortality in patients awaiting liver transplantation. The UKELD (United Kingdom Model of End-stage Liver Disease) score is based on the
same variables as MELD-Na and is used in the United Kingdom to determine the need for liver transplantation. A score ≥49 indicates a 9% 1-year risk of death and is the minimum score required for listing for liver transplantation for liver failure. Although these scores give a guide to prognosis, the course of cirrhosis is unpredictable, being heavily influenced by the incidence of sporadic decompensating events (e.g. sepsis, variceal bleeding, etc.).

### Acute on chronic liver failure

Acute on chronic liver failure (ACLF) is a term used to describe acute decompensation of chronic liver disease with features of liver failure (jaundice and coagulopathy) and other extra-hepatic organ failures. It is associated with a high short-term mortality. Common triggering events include alcoholic hepatitis, systemic infection or viral hepatitis. However up to 40% of patients have no identifiable precipitant. Persistent inflammation and immune dysfunction results in a systemic inflammatory response syndrome leading to extra-hepatic organ failure. The number of extra-hepatic organs involved determines prognosis. The 28-day mortality with single organ failure (typically renal failure or hepatic encephalopathy) is 23%, increasing to 32% in patients with two organ failures and >75% in patients with three or more organ failures. Management involves identification and treatment of the precipitating event and organ support as required.

### Portal hypertension

Portal hypertension frequently complicates cirrhosis but has other causes. The normal hepatic venous pressure gradient (HVPG – difference between the wedged hepatic venous pressure (WHVP) and free hepatic venous pressure (FHVP); see below) is 5–6 mmHg. Clinically significant portal hypertension is present when the gradient exceeds 10 mmHg and risk of variceal bleeding increases beyond a gradient of 12 mmHg. Causes are classified in accordance with the main sites of obstruction to blood flow in the portal venous system (Fig. 24.21). Extrahepatic portal vein obstruction is the usual source of portal hypertension in childhood and adolescence, while cirrhosis causes at least 90% of cases of portal hypertension in adults in developed countries. Schistosomiasis is the most common cause of portal hypertension worldwide but is infrequent outside endemic areas, such as Egypt.

### Clinical features

The clinical features result principally from portal venous congestion and collateral vessel formation (Box 24.33). Splenomegaly is a cardinal finding and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged more than 5 cm below the left costal margin in adults but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a ‘caput medusae’ (p. 860). Rarely, a large umbilical collateral vessel has a blood flow sufficient to give a venous hum on auscultation (Cruveilhier–Baumgarten syndrome). The most important collateral vessel formation occurs in the oesophagus and stomach, as this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids (which are no more common in portal hypertension than in the general population). Fetal hepatic results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

Asciites occurs as a result of renal sodium retention and portal hypertension that may be due, for example, to post-hepatic causes (hepatic outflow obstruction, p. 875) or cirrhosis.

The most important consequence of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the gastro-oesophageal junction, or from gastric varices. The size of these varices, endoscopic variceal features such as red spots and stripes, high portal pressure and liver failure are all factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates and NSAIDs, can also precipitate bleeding. Variceal bleeding is often severe, and recurrent if preventative treatment is not given.

Fig. 24.21 Classification of portal hypertension according to site of vascular obstruction. *Most common cause. Note that splenic vein occlusion can also follow pancreatitis, leading to gastric varices.

24.33 Complications of portal hypertension
- Variceal bleeding: oesophageal, gastric, other (rare)
- Congestive gastropathy
- Hypersplenism
- Ascites
- Iron deficiency anaemia
- Renal failure
- Hepatic encephalopathy

Pathophysiology
Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels, allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, lumbar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. As collateral vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

Investigations
The diagnosis is often made clinically. Portal venous pressure measurements are rarely needed for clinical assessment or routine management but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements are made by using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the WHVP. This is an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of 100 x 10⁹/L; values below 50 x 10⁹/L are uncommon. Leucopenia occurs occasionally but anaemia is seldom attributed directly to hypersplenism.

Endoscopy is the most useful investigation to determine whether gastro-oesophageal varices are present (see Fig. 24.17). When cirrhosis is diagnosed, endoscopy should be performed to screen for oesophageal varices (and repeated every 2–3 years if initially absent). However, this may not be needed in patients with a normal platelet count and low liver stiffness (<20kPa) who are at low risk of significant varices. Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as cirrhosis or portal vein thrombosis. CT and magnetic resonance angiography can identify the extent of portal vein clot and check hepatic vein patency.

Management
Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices is a common manifestation of chronic liver disease. In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but is still about 45% in those with poor liver function (i.e. Child–Pugh C).

The management of portal hypertension is largely focused on the prevention and/or control of variceal haemorrhage. It is important to remember, though, that bleeding can also result from peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail on page 797.

Primary prevention of variceal bleeding
If non-bleeding varices are identified at endoscopy, non-selective β-adrenoceptor antagonist (β-blocker) therapy with propranolol (80–160mg/day) or nadolol (40–240mg/day) is effective in reducing portal venous pressure. Administration of these drugs at doses that reduce the heart rate by 25% has been shown to be effective in the primary prevention of variceal bleeding. In patients with cirrhosis, treatment with propranolol reduces variceal bleeding by 47% (number needed to treat for benefit NNT₉ 10), death from bleeding by 45% (NNT₉ 25) and overall mortality by 22% (NNT₉ 16). The efficacy of β-blockers in primary prevention is similar to that of prophylactic banding, which may also be considered, particularly in patients who are unable to tolerate or adhere to β-blocker therapy. Candesartan, a non-cardioselective vasodilating β-blocker, is also effective and may be better tolerated at doses of 6.25–12.5mg/day.

Management of acute variceal bleeding
The priority in acute bleeding is to restore the circulation, not least because shock reduces liver blood flow and causes further deterioration of liver function. However, restrictive transfusion (aiming for a haemoglobin level >7g/dL) is associated with better outcomes than liberal transfusion. The source of bleeding should always be confirmed by endoscopy because about 20% of patients are bleeding from non-variceal lesions. Management of acute variceal bleeding is described in Box 24.34 and illustrated in Fig. 24.22. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as intravenous cephalosporin or piperacillin/tazobactam, because sepsis is common and treatment with antibiotics improves survival. The measures used to control acute variceal bleeding include vasoactive medications (e.g. terlipressin), endoscopic therapy (banding), balloon tamponade and TIPSS.

Pharmacological reduction of portal venous pressure Terlipressin is a synthetic vasopressin analogue that, in contrast to vasopressin, can be given by intermittent injection rather than continuous infusion. It reduces
portal blood flow and/or intrahepatic resistance and hence brings down portal pressure. It lowers mortality in the setting of acute variceal bleeding. The dose of terlipressin is 2 mg intravenously 4 times daily until bleeding stops, and then 1 mg 4 times daily for up to 72 hours. Caution is needed in patients with severe ischaemic heart disease or peripheral vascular disease because of the drug’s vasoconstrictor properties. In countries where terlipressin is not available, octreotide is a frequently used alternative.

**Variceal ligation (‘banding’)** This is the most widely used initial treatment and is undertaken, if possible, at the time of diagnostic endoscopy (see Fig. 24.17C). It stops variceal bleeding in over 90% of patients and can be repeated if bleeding recurs. Band ligation involves the varices being sucked into a cap placed on the end of the endoscope, allowing them to be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 2–4 weeks until all varices are obliterated. Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than sclerotherapy, a technique in which varices were injected with a sclerosing agent, and has largely replaced it. Prophylactic acid suppression with proton pump inhibitors may reduce the risk of secondary bleeding from banding-induced ulceration.

In the case of gastric varices, banding is less effective and so endoscopic therapy relies on injection of agents such as thrombin or cyanoacrylate glue directly into the varix to induce thrombosis. Although highly effective, cyanoacrylate injection treatment may be complicated by ‘glue embolism’ to the lungs.

Active bleeding may make endoscopic therapy difficult. Protection of the patient’s airway with endotracheal intubation aids the endoscopist, facilitating therapy and significantly reducing the risk of pulmonary aspiration.

**Balloon tamponade** This technique employs a Minnesota tube, which consists of two balloons that can be positioned in the fundus of the stomach and in the lower oesophagus, respectively (Fig. 24.23). Additional lumens allow contents to be aspirated from the stomach and from the oesophagus. This technique may be used in the event of life-threatening haemorrhage if early endoscopic therapy is not available or is unsuccessful.

Endotracheal intubation prior to tube insertion reduces the risk of pulmonary aspiration. The tube should be passed through the mouth into the stomach. The gastric balloon should be inflated with 200–250 mL of air, and gentle traction applied to compress the gastro-oesophageal junction. Inadvertent inflation in the oesophagus can result in oesophageal rupture so, ideally, the gastric balloon should be inflated under direct endoscopic vision. Tamponade of the gastro-oesophageal junction with the gastric balloon will almost always control bleeding from oesophageal varices and inflation of the oesophageal balloon is rarely required. If the oesophageal balloon needs to be used because of continued bleeding, pressure should be monitored with a sphygmomanometer (to maintain <40 mmHg) and it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Balloon tamponade is only a bridge to more definitive therapy. Novel endoscopic therapies such as self-expanding removable oesophageal stents and haemostatic powder spray also appear to be effective short-term alternatives in small case series.

**TIPSS** This technique uses a stent placed between the portal vein and the hepatic vein within the liver to provide a portosystemic shunt and reduce portal pressure (Fig. 24.24). It is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically, coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents further variceal bleeding, and is an effective treatment for both oesophageal and gastric varices. Further bleeding necessitates investigation and treatment (e.g. angioplasty) because it is usually associated with shunt narrowing or occlusion. Hepatic encephalopathy occurs in up to a third of patients following TIPSS and may require reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved.

---

**Fig. 24.22 Management of acute bleeding from oesophageal varices.** (TIPSS = transjugular intrahepatic portosystemic stent shunt)
Secondary prevention of variceal bleeding

Beta-blockers are used as a secondary measure to prevent recurrent variceal bleeding. Following successful endoscopic therapy, patients should be entered into an oesophageal banding programme with repeated sessions of therapy at 2–4-week intervals until the varices are obliterated. There is some evidence that early TIPSS after successful endoscopic therapy may improve survival in selected patients with advanced liver disease.

Congestive ‘portal hypertensive’ gastropathy

Long-standing portal hypertension causes chronic gastric congestion, which is recognisable at endoscopy as multiple areas of punctate erythema (‘portal hypertensive gastropathy’ or ‘snakeskin gastropathy’) in the proximal stomach. Similar lesions may also occur more distally in the gastrointestinal tract (enteropathy and colopathy). These areas may become eroded, causing oozing from multiple sites. Acute bleeding can occur but repeated minor bleeding causing iron deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using propranolol (80–160 mg/day) is the best initial treatment. In selected cases TIPSS procedure can be considered.

Gastric antral vascular ectasia (GAVE) is an alternative cause of mucosal oozing in patients with cirrhosis. This is characterised by red spots in the distal stomach, often arranged in stripes around the pylorus (‘watermelon stomach’). Therapy for GAVE is focused on endoscopic ablation using argon plasma coagulation (APC) or radiofrequency ablation (RFA).

Infections and the liver

The liver may be subject to a number of different infections. These include hepatotropic viral infections and bacterial and protozoal infections. Each has specific clinical features and requires targeted therapies.

Viral hepatitis

This must be considered in anyone presenting with hepatic liver blood tests (high transaminases). The causes are listed in Box 24.35.

All these viruses cause illnesses that have similar clinical and pathological features and are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in Box 24.36.

Clinical features of acute infection

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow and abdominal discomfort is common. Dark urine and pale stools may precede jaundice. There are usually few physical signs. The liver is often tender but only minimally enlarged. Occasionally, mild splenomegaly and

Portosystemic shunt surgery  Surgery prevents recurrent bleeding but carries a high mortality and often leads to encephalopathy. In practice, portosystemic shunts are now reserved for when other treatments have not been successful and are offered only to patients with good liver function.

Oesophageal transection  Rarely, surgical transection of the varices may be performed as a last resort when bleeding cannot be controlled by other means but operative mortality is high.

24.37 Complications of acute viral hepatitis

- Acute liver failure
- Cholestatic hepatitis (hepatitis A)
- Aplastic anaemia
- Chronic liver disease and cirrhosis (hepatitis B and C)
- Relapsing hepatitis

Cervical lymphadenopathy are seen. These features are more frequent in children or those with Epstein–Barr virus (EBV) infection. Symptoms rarely last longer than 3–6 weeks. Complications may occur but are rare (Box 24.37).

**Investigations**

A hepatic pattern of LFTs develops, with serum transaminases typically between 200 and 2000 U/L in an acute infection (usually lower and fluctuating in chronic infections). The ALP rarely exceeds twice the upper limit of normal. The plasma bilirubin and prothrombin time (PT) reflect the degree of liver damage. Prolongation of the PT rarely exceeds 25 seconds, except in rare cases of acute liver failure. The white cell count is usually normal with a relative lymphocytosis. Serological tests confirm the aetiology of the infection.

**Management**

Most individuals do not need hospital care. Drugs such as sedatives and narcotics, which are metabolised in the liver, should be avoided. Alcohol should not be taken during the acute illness. Elective surgery should be avoided in cases of acute viral hepatitis, as there is a risk of post-operative liver failure.

Liver transplantation is very rarely indicated for acute viral hepatitis complicated by liver failure.

**Hepatitis A**

The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal–oral route. Risk of infection is associated with a lack of safe water and poor sanitation. In occasional outbreaks, water and shellfish have been the vehicles of transmission. Infection may be asymptomatic or produce symptoms after an average incubation period of 28 days. The likelihood of symptoms relates to age, with most children under 6 years of age having no symptoms but most adults developing jaundice. Up to 30% of adults will have serological evidence of past infection but give no history of jaundice. Infected individuals excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and then for a further 2 weeks or so.

In contrast to hepatitis B and C, chronic infection does not occur. Almost all cases will recover fully with lifelong immunity, but a very small proportion develop acute liver failure (0.1%) and may die. Infection in patients with pre-existing chronic liver disease may cause serious or life-threatening disease. In adults, a cholestatic phase with elevated ALP levels may complicate infection.

**Investigations**

Diagnosis of HAV infection is based on antibody testing. Only one HAV antigen has been found and infected people make an antibody to this antigen (anti-HAV). Anti-HAV immunoglobulin (Ig) M antibody is detectable in the blood 5–10 days before the onset of symptoms and falls to low levels within about 3 months of recovery; so is diagnostic of acute HAV infection. Anti-HAV IgG antibody persists for years after infection, and is a marker of previous HAV infection with resulting immunity.

**Management**

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated virus vaccine. Immunisation should be considered for those at particular risk, such as people travelling to endemic areas, close contacts of HAV-infected patients, older individuals, those with other major disease (including chronic liver disease) and perhaps pregnant women.

Immediate protection can also be provided by immune serum globulin if this is given soon after exposure to the virus. The protective effect of immune serum globulin is attributed to its anti-HAV content. Intramuscular injection of immune serum globulin is recommended for close contacts of infected individuals who are less able to respond to
vaccination, such as those aged 60 years or over, immunocompromised individuals or those with chronic liver disease. It may also be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families.

There is no role for antiviral drugs in the therapy of HAV infection.

**Hepatitis B**

The hepatitis B virus (HBV) consists of a core containing DNA and a DNA polymerase enzyme which is induced by virus replication, surrounded by surface protein (Fig. 24.25). The virus and an excess of its surface protein (known as hepatitis B surface antigen, HBsAg) circulate in the blood. The virus replicates and assemblies within hepatocytes but is not directly cytotoxic; hepatocyte damage occurs during immune-mediated clearance of infected hepatocytes.

Hepatitis B is one of the most common causes of chronic liver disease and hepatocellular carcinoma worldwide. Approximately 250 million people have chronic HBV infection. There is large regional variation, with the highest rates seen in the Western Pacific and African regions.

Hepatitis B can cause acute or chronic infection. The risk of developing chronic HBV infection depends on the source and timing of exposure. Infections may occur via a number of routes (Box 24.38). In endemic areas, vertical transmission from mother to child in the perinatal period is the most common cause of infection and carries the highest risk of ongoing chronic infection (90%–95%). In contrast, exposure to HBV at an older age is much more likely to result in an acute hepatitis, with chronic infection developing in less than 5% of adult-acquired HBV.

In perinatal infection, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Although HBV-specific T-cells are detectable in this setting, they are weak and functionally impaired. The mechanisms underlying this are incompletely understood.

Chronic hepatitis can lead to cirrhosis or hepatocellular carcinoma, usually after decades of infection (Fig. 24.26). Chronic HBV infection is a dynamic process that can be divided into five phases (Box 24.39); these are not necessarily strictly sequential, however, and not all patients will go through all phases. Phases are considered as either ‘infection’ where circulating HBsAg is detectable but is not resulting in any current liver injury, or ‘hepatitis’ where this is accompanied by liver inflammation and fibrosis.

**Investigations**

Assessment of hepatitis B infection relies on looking at a combination of viral markers (surface antigen, e-antigen and viral load) and liver markers (ALT and fibrosis markers) to determine the stage of disease.

---

**Fig. 24.25 Schematic diagram of the hepatitis B virus.** Hepatitis B surface antigen (HBsAg) is a protein that makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein that makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg that can be found in the blood and indicates infectivity. (HBV = hepatitis B virus)}

---

### Vertical transmission
- Hepatitis B surface antigen (HBsAg)-positive mother (especially if e-antigen-positive)

### Horizontal transmission
- Sexual transmission
- Intravenous drug use
- Infected unscreened blood products
- Tattoos/acupuncture needles
- Needlestick injury
- Sharing toothbrush/razor
- Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)

---

**Serology**

HBV contains several antigens to which infected persons can make immune responses (Fig. 24.27); these antigens and their antibodies are important in identifying the stage of HBV infection (see Box 24.39 and Box 24.40), in addition to direct assessment of viral load by polymerase chain reaction (PCR) for HBV DNA.

**Hepatitis B surface antigen** Hepatitis B surface antigen (HBsAg) is the main indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. The exception is in acute liver failure from hepatitis B, where the liver damage is mediated by viral clearance and so HBsAg may be negative at presentation, with evidence of recent infection provided by the presence of hepatitis B core (anti-HBc) IgM (see below). In resolving acute HBV infection, antibody to HBsAg (anti-HBs) usually appears after about 3–6 months and persists for many years or perhaps permanently. Anti-HBs implies either a previous infection, in which case anti-HBc (see below) is usually also present, or previous vaccination, in which case anti-HBc is not present.

**Hepatitis B core antigen** Hepatitis B core antigen (HBcAg) is not found in the blood, but antibody to it (anti-HBc) appears early in the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type, with IgG antibody appearing later (see Fig. 24.27 and Box 24.40).

**Hepatitis B e antigen** Hepatitis B e antigen (HBeAg) is part of the core antigen that is detectable in the blood and can be used as an indicator of viral replication. Seroconversion to e antigen (i.e., loss of HBeAg and development of anti-HBe antibody) indicates a partial immune control of the virus and is associated with a significant drop in viral load. This typically occurs after 10–30 years in perinatally acquired infection, but within 3–6 months in adult-acquired acute infections.

**Viral load and genotype**

HBV-DNA can be measured by PCR in the blood. Viral loads are usually highest (in excess of 10⁶ copies/mL) in HBeAg-positive infection, making this the most infectious phase. Once patients undergo HBeAg seroconversion, viral loads drop to levels of 10³ copies/mL in HBeAg-negative infection. Around 15%–20% of patients will subsequently develop further rises in viral load, due to mutations in the pre-core or core promoter region (Fig. 24.28). Such patients are classified as having HBeAg-negative chronic hepatitis.

Measurement of viral load is important in detecting flares of HBeAg-negative hepatitis and in monitoring response to antiviral therapy. Ten HBV genotypes (A–J) can also be identified using PCR. These affect the likelihood of response to pegylated interferon.

**Management of acute hepatitis B**

Full spontaneous recovery occurs in more than 95% of adults following acute HBV infection. Fulminant liver failure due to acute hepatitis B
Management of chronic hepatitis B

Once hepatitis B infection has been present for more than 6 months, spontaneous clearance is uncommon. Most patients with chronic hepatitis B are asymptomatic and develop complications, such as cirrhosis and hepatocellular carcinoma, only after many years (see Fig. 24.26). Fibrosis accumulates during periods of liver injury (the ‘hepatitis’ phases) and results in cirrhosis in 15%–20% of patients with chronic HBV over 5–20 years. The rate of progression to cirrhosis is higher in HBeAg-negative hepatitis (8%–10% incidence per annum) than HBeAg-positive hepatitis (2%–5% per annum).

The ideal goal of treatment would be to achieve long-term viral clearance with loss of HBsAg, but this is rarely achieved with current therapies. Instead, treatment is aimed at suppressing viral replication to prevent disease progression to cirrhosis or hepatocellular carcinoma. The goals of treatment are therefore HBeAg seroconversion, reduction in HBV-DNA and normalisation of the LFTs. Only a proportion (10%–40%) of patients with chronic hepatitis B will require treatment. This is usually targeted at those in the ‘hepatitis’ phases with high viral load and
accompanying liver injury, either in terms of necroinflammation (raised ALT) or established fibrosis (on biopsy or raised liver stiffness on transient elastography). All patients with cirrhosis should be treated to prevent decompensation. Treatment may also be initiated during pregnancy in the absence of liver injury to prevent mother-to-child transmission.

Different types of drug are used to treat hepatitis B: direct-acting nucleoside/nucleotide analogues and pegylated interferon-alfa.

Direct-acting nucleoside/nucleotide antiviral agents

Orally administered nucleoside/nucleotide antiviral agents are the mainstay of therapy. These act by inhibiting the reverse transcription of pre-genomic RNA to HBV-DNA by HBV-DNA polymerase but do not directly affect the covalently closed circular DNA (cccDNA) template for viral replication, and so relapse is common if treatment is withdrawn. One major concern is the selection of antiviral-resistant mutations with long-term treatment. This is particularly important with some of the older agents, such as lamivudine, as mutations induced by previous antiviral exposure may also induce resistance to newer agents. Entecavir and tenofovir (see below) are potent antivirals with a high barrier to genetic resistance and so are the most appropriate first-line agents.

Lamivudine

Although initially effective, long-term therapy is often complicated by the development of HBV-DNA polymerase mutants (e.g. the ‘YMDD variant’), which lead to viral resistance. These occur in around half of patients after 3 years and are characterised by a rise in viral load during treatment. Outside resource-limited settings, this agent is now seldom used for the treatment of HBV but may be used to prevent reactivation in patients with past HBV infection (HBsAg-negative but HBeAg-positive) if they are undergoing treatment with rituximab or chemotherapy.

Entecavir and tenofovir

Monotherapy with entecavir or tenofovir is substantially more effective than lamivudine in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis. Antiviral resistance mutations occur very rarely; in <1% after 5 years of entecavir and with no evidence of resistance after 8 years of tenofovir. Both drugs have action against human immunodeficiency virus (HIV) and so their use as monotherapy is contraindicated in HIV-positive patients, as it may lead to HIV antiviral drug resistance. Current European guidelines advise that the other nucleoside/nucleotide antivirals should not be used as first-line monotherapy due to the induction of viral mutations, unless entecavir or tenofovir are not available or appropriate.

Pegylated interferon-alfa

Pegylated interferon-alfa (PEG-IFN) acts by augmenting the host immune response. This is most effective in patients with a pre-treatment low viral load and serum transaminases greater than twice the upper limit of normal. Treatment is for a finite period (typically around 1 year), and is associated with higher rates of HBsAg and HBeAg seroconversion than nucleoside/nucleotide agents but with greater side-effects. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. In HBeAg-positive chronic hepatitis, PEG-IFN results in sustained HBeAg seroconversion in around 30%, and HBsAg seroconversion in 3%–5%. Response rates are higher in those with genotype A or B virus, and those with low viral load and high ALT. Sustained response rates are lower in HBeAg-negative chronic hepatitis.

Liver transplantation

Patients with advanced liver disease or hepatocellular carcinoma (HCC) may require liver transplantation. The use of nucleoside/nucleotide analogues post-transplant (with hepatitis B immunoglobulin in high-risk individuals) has made recurrent disease due to graft re-infection very uncommon, and outcomes are comparable with other indications.
Hepatocellular carcinoma risk

Chronic HBV infection is associated with an increased risk of hepatocellular carcinoma, even in the absence of cirrhosis. This risk increases with age, male sex, smoking, diabetes, family history of HCC and high viral loads. A number of scoring systems (such as REACH-B and PAGE-B) have been developed to identify high-risk non-cirrhotic patients who may benefit from HCC screening.

Prevention

Individuals are most infectious when high levels of HBV-DNA are present in the blood, typically in the HBeAg-positive infection phase. HBV-DNA can be found in saliva, urine, semen and vaginal secretions (although urine is not usually considered to be capable of transmitting infection). The virus is about ten times more infectious than hepatitis C.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active immunisation in 95% of normal individuals. The vaccine should be offered to those at increased risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 24.41). The vaccine is ineffective in those already infected by HBV. Following known exposure, infection can also be prevented or minimised by the intramuscular injection of specific hepatitis B immunoglobulin (HBIG) prepared from blood containing anti-HBs. This should be given within 48 hours, or at most a week, of exposure to infected blood (e.g. needlestick injury, contamination of cuts or mucous membranes). Vaccine can be given together with HBIG (active-passive immunisation).

Neonates born to hepatitis B-infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

Co-infection with HIV

Around 10% of the HIV-infected population has concurrent HBV and this figure may be as high as 25% in areas where both viruses are prevalent. Up to half of injection drug users with HIV are co-infected with HBV. Co-infection increases the morbidity and mortality compared to either infection alone; there are greater levels of HBV viraemia, faster progression to chronic infection and greater risk of cirrhosis and hepatocellular carcinoma than with HBV infection alone. The immunosuppression that is seen in HIV infection can lead to loss of anti-HBs antibodies, reactivation of infection and a poorer antibody response to HBV vaccination. Pregnancy poses particular problems in co-infected patients, with increased risk of perinatal transmission of HBV to the child.

Treatment can also be problematic. Several nucleoside analogues have dual antiviral activity and some regimens have been associated with emergence of drug resistance. Co-infection is also associated with diminished response to interferons and increased resistance to lamivudine in some patients. Co-infection should be managed by specialists with expertise in this area and combinations of antiviral agents need to be thought through carefully. Antiviral therapy should be considered for co-infected pregnant women, using drugs with dual activity, e.g. tenofovir with emtricitabine or lamivudine.

Globally, there is a need to identify co-infected patients earlier, especially in endemic areas, as well as a need for early effective interventions, particularly in pregnant women, to reduce perinatal transmission.

Hepatitis D (Delta virus)

The hepatitis D virus (HDV) is an RNA-defective virus that has no independent existence; it requires HBV for replication and has the same sources and modes of spread. It can infect individuals simultaneously with HBV or can superinfect those who already have chronic HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals with chronic HBV can cause acute hepatitis with spontaneous recovery, and occasionally there is simultaneous cessation of the chronic HBV infection. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a worldwide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers with HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

Investigations

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV, followed by full recovery, is associated with the appearance of low titres of anti-HDV IgM within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Super-infection of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

Management

Effective management of hepatitis B prevents hepatitis D.

Hepatitis C

This is caused by an RNA flavivirus. Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are identified only when they develop chronic liver disease. Around 70% of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare. It is estimated that around 70 million individuals have chronic hepatitis C worldwide, with the highest prevalence in the Eastern Mediterranean region. There is no active or passive protection against hepatitis C virus (HCV).

Hepatitis C infection is usually identified in asymptomatic individuals screened because they have risk factors for infection, such as previous injecting drug use (Box 24.42), or have incidentally been found to have abnormal liver blood tests. Although most people remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and is unrelated to the degree of liver damage.

If hepatitis C infection is left untreated, progression from chronic hepatitis to cirrhosis may occur, with 20% developing cirrhosis over 20 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV), prothrombotic states and heavy alcohol misuse. Once cirrhosis is present, 2%–5% per year will develop primary hepatocellular carcinoma, although this rate falls by around 75% following successful antiviral therapy.

Investigations

Serology and virology

The HCV genome encodes a large polypeptide precursor that is modified post-translationally to at least 10 proteins, including several antigens that give rise to antibodies in an infected person; these are used in diagnosis. Following an acute infection (such as a needlestick injury), HCV RNA can be detected in the blood within 2–4 weeks but it may take 6–12 weeks for antibodies to appear. Anti-HCV antibodies persist in serum even after

24.41 At-risk groups meriting hepatitis B vaccination in low-endemic areas

- Parenteral drug users

- Patients with chronic liver disease
- Medical, nursing and laboratory personnel
viral clearance, whether spontaneous or post-treatment. Anti-HCV antibodies are used as the initial screening test for chronic infection but if positive, the presence of serum HCV RNA or hepatitis C core antigen is required to confirm active infection. In cases of suspected acute infection, negative testing should be repeated after 4 weeks.

Molecular analysis
There are six common viral genotypes, the distribution of which varies worldwide. The most common genotypes are 1 (45%) and 3 (25%). Genotype has no effect on progression of liver disease but historically had a major effect on response to treatment: genotype 1 was less easy to eradicate than genotypes 2 and 3 with traditional pegylated interferon alfa-ribavirin-based treatments. All genotypes now have highly successful treatment options, although genotype may still be used to guide the choice of direct-acting antiviral drugs.

Liver function tests
LFTs may be normal or show fluctuating serum transaminases between 50 and 200 U/L. Jaundice can occasionally occur during acute infection and confers an increased likelihood of spontaneous viral clearance, but otherwise only appears in end-stage cirrhosis.

Fibrosis assessment
Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis. This should be assessed at diagnosis using transient elastography, blood biomarkers or non-invasive fibrosis scoring systems such as the Fibrosis-4 (FIB4) score or aspartate aminotransferase to platelet ratio index (APRI). Where there is diagnostic uncertainty, a liver biopsy may be required to stage the extent of liver damage.

Management
The aim of treatment is to eradicate infection and all patients with chronic HCV infection should be treated where possible. Sustained virological response (SVR) refers to undetectable HCV RNA at least 12 weeks after treatment completion, and carries a very low chance (<1%) of subsequent relapse. In recent years, there have been substantial advances in treatment, with rates of SVR rising from less than 40% a decade ago to levels approaching 100% with newer direct-acting antivirals (DAAs). Whilst the cost of these new treatments initially posed a significant financial challenge, the price of DAAs has fallen significantly in recent years and the challenges now include identification and engagement of patients with infection.

Until 2013, the treatment of choice was combination therapy with pegylated interferon and ribavirin for up to 48 weeks. Treatment had many side-effects and a low SVR rate of 40%–70% depending on genotype.

Since 2013, new classes of DAAs have allowed interferon-free regimens with substantially shorter treatment duration, minimal side-effects and high cure rates. There are four main classes of DAA, which are defined according to their mechanism of action and therapeutic target (Box 24.43). These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt viral replication (Fig. 24.29). These drugs are now frequently combined into single pill combinations that can be taken once daily for 8–12 weeks with SVR rates of over 95%. Whilst some DAA combinations are only licensed for specific viral genotypes, several pan-genotypic treatments are now available.

Liver transplantation should be considered when complications of cirrhosis occur. However, DAAs can be safely used even in patients with decompensated cirrhosis, and successful treatment can be associated with an improvement in liver function. It is therefore becoming less common to require liver transplantation for liver failure secondary to hepatitis C, although it may still be required for hepatocellular carcinoma. Whilst most patients will now be able to have successful anti-viral treatment before transplantation, DAAs can also be used post-transplant and recurrent hepatitis C in the transplanted liver is now very rare.

Hepatitis E
Hepatitis E virus (HEV) is an RNA virus that is now thought to be the most common cause of acute viral hepatitis worldwide. Four major genotypes are described. Genotypes 1 and 2 exclusively infect humans via the faecal–oral route and cause waterborne epidemics, mainly in Asia. Genotypes 3 and 4 are mostly zoonotic (in pigs, wild boars and deer) and are transmitted to humans through undercooked meat. HEV can rarely be transmitted by blood transfusion, and blood donations in the United Kingdom are now routinely screened for hepatitis E.

HEV causes a self-limiting acute hepatitis that does not require any specific treatment. However, it can cause chronic hepatitis, progressing to cirrhosis, in immunocompromised patients, especially organ-transplant recipients. This may require a reduction in the level of immunosuppression and/or treatment with ribavirin.

Infection with genotype 1 or 2 virus during pregnancy carries a high risk of acute liver failure, which has a high mortality. Hepatitis E also causes more severe disease in those with underlying cirrhosis, resulting in decompensation or acute-on-chronic liver failure. Extrahepatic manifestations are increasingly recognised and include neurological problems such as Guillain–Barré syndrome and neuropsychic amyotrophy.

Diagnosis of acute infection is usually based on detection of anti-HEV IgM antibodies but it is possible to measure HEV RNA or capsid antigen in the blood and stool (especially in immunocompromised patients).

Other forms of viral hepatitis
Non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Although the viruses
above account for the majority of clinically significant hepatitis infections, other viruses can affect the liver. Cytomegalovirus and EBV infection causes abnormal LFTs in most patients and occasionally jaundice occurs. Herpes simplex is a rare cause of hepatitis in adults, most of whom are immunocompromised but can be very severe in pregnancy. Abnormal LFTs are also common in chickenpox, measles, rubella, acute HIV and COVID-19 infection.

**HIV infection and the liver**

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 24.44. This topic is discussed in more detail in Chapter 14. Co-infection with HIV and HBV is discussed on page 889.

**Liver abscess**

Liver abscesses are classified as pyogenic (bacterial), hydatid (protozoal) or amoebic.

**Pyogenic liver abscess**

Pyogenic liver abscesses are uncommon but important because they are potentially curable but carry significant morbidity and mortality if untreated. The mortality of liver abscesses is 5%–25%. Mortality is higher in those with multiple abscesses, underlying malignancy or other comorbidities, and delayed diagnosis.

**Pathophysiology**

Infection can reach the liver in several ways (Box 24.45). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. They can also complicate dental sepsis or colonic pathology, e.g., cancer, diverticulitis or inflammatory bowel disease causing portal pyaemia. Abscesses complicating suppurative appendicitis used to be common in young adults but are now rare. Immunocompromised or diabetic patients are particularly likely to develop liver abscesses. Multiple abscesses are usually due to biliary obstruction and may be polymicrobial. Escherichia coli, Klebsiella pneumonia and Streptococcus milleri are the most common organisms; anaerobes such as Bacteroides can often be found when infection has been transmitted from large bowel pathology.

**Clinical features**

Patients are generally ill with fever and sometimes rigors and weight loss. Right upper quadrant abdominal pain is common, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Tender hepatomegaly is found in more than 50% of patients. Mild jaundice may be present, becoming severe if large abscesses cause biliary obstruction. Atypical presentations are common and include anorexia, diarrhoea, dyspnoea and pyrexia of unknown origin. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

**Investigations**

A raised white cell count and neutrophilia is common. Alkaline phosphatase is often raised and albumin levels are low. Blood cultures are
positive in 50%–80%. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Liver imaging is key; ultrasound will detect at least 80% of pyogenic abscesses and CT with contrast will detect over 95%. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. Abscesses caused by gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

Management

Pending the results of culture and blood and pus from the abscess, treatment should be commenced with a combination of antibiotics, such as ampicillin, gentamicin and metronidazole. Percutaneous aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or not responding to antibiotics. Any associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Surgical abscess drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or "pseudotumour".

Hydatid cysts and amoebic liver abscesses

These are described on pages 342 and 330.

Leptospirosis

This is described on page 305.

Alcohol-related liver disease

Alcohol is one of the most common causes of chronic liver disease worldwide, with consumption continuing to increase in some countries. Excessive alcohol consumption produces a spectrum of effects on the liver. Almost all heavy drinkers will have alcohol-related fatty liver, but only a minority will develop clinically significant liver disease (alcoholic hepatitis or cirrhosis). A number of factors influence the risk of developing the more severe features of alcohol-related liver disease (ALD):

- **Amount of alcohol consumed.** In the UK, a "unit" of alcohol contains 8 g of ethanol (Box 24.46). There is significant variability between countries in advice with regard to alcohol consumption but current UK guidelines recommend drinking less than 14 units of alcohol per week. This threshold is based on a wide range of health issues, including cancer risk. The threshold of alcohol consumption required to develop liver disease varies considerably between individuals but begins at around 30 g/day (25–30 units/week) of ethanol. However, there is not a linear relationship between dose and liver damage. For many, consumption of more than 80 g/day, for more than 5 years, is required to confer significant risk of advanced liver disease. The average alcohol consumption of a man with cirrhosis is 160 g/day for over 8 years. However, even at this level of consumption, many patients will not develop advanced liver disease.
- **Drinking pattern.** There are conflicting data with regard to drinking pattern but it is generally thought that liver damage is more likely to occur in continuous rather than intermittent or "binge" drinkers, as this pattern gives the liver a chance to recover. It is therefore recommended that people should have at least two alcohol-free days each week. The type of beverage does not affect risk.
- **Sex.** Women who drink heavily are at higher risk of developing cirrhosis than men. This may relate to the higher blood ethanol levels seen in women compared to men after consuming the same amount of alcohol.
- **Genetics.** Genetic factors predispose to both alcohol use disorders and risk of disease progression. Polymorphisms in genes involved in alcohol metabolism (alcohol dehydrogenase and acetaldehyde dehydrogenase) and in neurotransmitter pathways (GABA receptor A2) are linked to alcohol dependence. The patatin-like phospholipase domain-containing 3 (PNPLA3) gene, also known as adiponutrin, is an important susceptibility gene for cirrhosis in both ALD and NAFLD (see next section).
- **Nutrition.** Being either obese or underweight increases mortality in alcohol-related liver disease. Ethanol itself produces 7 kcal/g (29.3 kJ/g) and many alcoholic drinks also contain sugar, which further increases the caloric value and may contribute to weight gain. Excess alcohol consumption is also frequently associated with nutritional deficiencies such as thiamine and folate deficiency.
- **Coexistent liver disease.** Patients with coexistent chronic hepatitis C or NAFLD who drink heavily have accelerated disease progression compared with non-drinkers.

Pathophysiology

Alcohol reaches peak blood concentrations after about 20 minutes, although this may be influenced by stomach contents. It is metabolised almost exclusively by the liver via one of two pathways (Fig. 24.30). Approximately 80% of alcohol is metabolised by alcohol dehydrogenase to acetaldehyde, and then by acetaldehyde dehydrogenase to acetate. This process converts NAD (nicotinamide adenine dinucleotide) to NADH, altering the redox potential of the cell. Up to 20% of alcohol is metabolised by the microsomal ethanol-oxidising system (MEOS), predominantly through the inducible cytochrome p450 2E1, also generating acetaldehyde along with oxygen free radicals. The CYP2E1 enzyme also metabolises acetylmethionine, and hence chronic alcoholics are more susceptible to hepatotoxicity from low doses of paracetamol. Acetaldehyde from either pathway is toxic and causes structural alterations of cellular proteins. This results in altered mitochondrial function and generation of reactive oxygen species, leading to oxidative stress. The altered ratio of reduced/oxidised NAD interrupts beta-oxidation of fatty acids and causes upregulation of sterol regulatory element-binding protein 1 (SREBP1), promoting fatty acid synthesis. Damage to hepatocytes leads to stimulation of immune cells via damage-associated molecular patterns (DAMPs) such as mitochondrial DNA or necrotic debris. Alcohol also affects the gut leading to dysbiosis and increased gut permeability, delivering pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharide and bacterial DNA via the portal vein which stimulate immune cells, leading to release of tumour necrosis factor alpha (TNF-α) and interleukin (IL)-1, IL-2 and IL-8. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 24.4).

The pathological features of ALD are shown in Box 24.47. The most common manifestation is accumulation of triglycerides within hepatocytes (hepatic steatosis), or alcohol-related fatty liver. This progresses in some patients to cause hepatocyte injury and inflammation, or steatohepatitis. This can present acutely with a clinical syndrome of rapid onset jaundice (alcoholic hepatitis) or can result in progressive fibrosis leading
to cirrhosis; these two presentations can coexist. Iron deposition is common and does not necessarily indicate haemochromatosis. Fig. 24.31 shows the histological features of alcohol-related liver disease, which are identical to those of non-alcoholic steatohepatitis.

**Clinical features**

Three types of ALD are recognised (Box 24.48) but these may overlap. Alcohol misuse may also cause damage of other organs and this should be specifically looked for (see Box 31.24). Dupuytren's contracture (thickening of the palmar fascia) is associated with chronic alcohol excess, but is not predictive of underlying liver disease.

**Alcohol-related fatty liver disease**

Alcohol-related fatty liver disease (AFLD) usually presents with an incidental finding of elevated transaminases or an echogenic liver on ultrasound. It is generally asymptomatic, has a good prognosis and steatosis usually disappears within 3 months of abstinence.

**Alcoholic hepatitis**

Alcoholic hepatitis (AH) presents with rapid onset jaundice in the context of recent heavy alcohol use. This is commonly associated with tender hepatomegaly and features of the systemic inflammatory response syndrome. Unlike other types of hepatitis, the ALT level is only mildly raised.
(<300) and may even be normal, but the AST/ALT ratio is often greater than 1.5–2. It carries a significant short-term risk of death, often due to sepsis or renal failure. Severe AH is associated with a 15% 1-month mortality and 50% 1-year mortality. Cirrhosis may coexist in patients with acute alcoholic hepatitis. Patients often deteriorate during the first 1–3 weeks in hospital. Even if they abstain, it may take up to 6 months for jaundice to resolve. In patients presenting with jaundice who subsequently abstain, the 3- and 5-year survival is 70%. In contrast, those who continue to drink have 3- and 5-year survival rates of 60% and 34%, respectively.

Alcoholic cirrhosis

Palmar erythema, spider naevi and gynaecomastia are more common in alcoholic cirrhosis than in cirrhosis of other aetiologies. Alcoholic cirrhosis often presents with a serious complication, such as variceal haemorrhage or ascites, and only half of such patients will survive for 5 years from presentation. However, most who survive the initial illness and who become abstinent will survive beyond 5 years.

Investigations

Investigations aim to establish alcohol misuse, exclude alternative or additional coexistent causes of liver disease, and assess the severity of liver damage. The clinical history from patient, relatives and friends is important to establish alcohol misuse duration and severity. Biological markers, particularly macrocytosis in the absence of anaemia, may suggest and support a history of alcohol misuse. A raised GGT is commonly seen in alcohol-related fatty liver and generally falls within 2–6 weeks of abstinence but is not specific and may also be elevated in the presence of other conditions, including NAFLD. Carbohydrate-deficient transferrin (CDT) is also a serum biomarker of recent alcohol excess.

The extent of fibrosis can be assessed using either serum fibrosis markers or transient elastography. A liver biopsy is occasionally required if there is diagnostic uncertainty.

In alcoholic hepatitis, a number of prognostic scoring systems are available. The prothrombin time (PT) and bilirubin are used to calculate a ‘modified discriminant function’ (mDF), also known as the Maddrey score, which enables the clinician to assess prognosis (serum bilirubin in µmol/L is divided by 17 to convert to mg/dL):

\[ DF = [4.6 \times \text{Increase in PT (sec)}] + \text{Bilirubin (mg/dL)} \]

Fig. 24.31 Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). Rate of progression is determined by environmental (dietary) and genetic factors. (FA = fatty acid; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha; VLDL = very low-density lipoprotein)
A value over 32 implies severe disease. Historically, this group had a 40%–50% 1 month mortality but this has dropped to 15% in a recent large study, reflecting improved medical management. A second scoring system, the Glasgow Alcoholic Hepatitis Score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis (Box 24.49). A score of 9 or more identifies an even higher risk group with a 60% 1-month mortality.

Management

Cessation of alcohol consumption is the single most important treatment and prognostic factor. Life-long abstinence is the best advice. General health and life expectancy are improved when this occurs, irrespective of the stage of liver disease. Abstinence is even effective at preventing progression, hepatic decompensation and death once cirrhosis is present. Treatment of alcohol dependency is discussed Chapter 31. In the acute presentation of ALD it is important to identify and anticipate alcohol withdrawal and Wernicke’s encephalopathy, in parallel with the liver disease.

Nutrition

Nutrition is very important, and calorie intake correlates with survival in severe alcoholic hepatitis. Enteral feeding via a fine-bore nasogastric tube may be needed in patients unable to meet their requirements.

Drug therapy

The optimal treatment of severe alcoholic hepatitis (Maddrey’s discriminative score > 32) has been widely debated. The STOPAH study was a large, multicentre, double-blind, randomised trial in patients with a clinical diagnosis of severe alcoholic hepatitis. This showed no effect of pentoxifylline (a weak anti-TNF agent) on survival. There was a borderline reduction in 28-day mortality with prednisolone, but no benefit by 3 months or 1 year. Prednisolone was associated with increased rates of sepsis and gastrointestinal bleeding. N-acetyl cysteine (NAC) may also limit oxidative stress but initial trials failed to show any benefit. A single trial has suggested a benefit of intravenous NAC in patients also treated with prednisolone. If the bilirubin has not fallen 7 days after starting glucocorticoids, the drugs are unlikely to reduce mortality and should be stopped.

Liver transplantation

ALD is a common indication for liver transplantation in Europe and the United States. The outcome of transplantation for ALD is good, with survival rates similar to other indications and if the patient remains abstinent there is no risk of disease recurrence. The challenge is to identify patients with an unacceptable risk of returning to harmful alcohol consumption. Many programmes require a 6-month period of abstinence from alcohol before a patient is considered for transplantation. Although duration of abstinence is only one factor in predicting risk of relapse and the length required is debatable, a period of abstinence will allow recovery of liver function sufficient to avoid transplantation in some, as well as identify those at highest risk of early recidivism. Transplantation for alcoholic hepatitis has been described in highly selected individuals with acceptable short-term outcomes but it is seldom performed due to concerns about longer-term risk of recidivism.

Non-alcoholic fatty liver disease

Increasingly sedentary lifestyles and changing dietary patterns mean that the prevalence of obesity and insulin resistance has increased worldwide, and so fat accumulation in the liver is a common finding during abdominal imaging studies and on liver biopsy. This results in a similar spectrum of liver disease to alcohol excess, so when these changes were observed in the absence of high alcohol consumption, this was called non-alcoholic fatty liver disease (NAFLD).

NAFLD includes a spectrum of progressive liver disease. The majority will have fatty infiltration alone (steatosis) but a minority (10%–20%) will develop accompanying inflammation (non-alcoholic steatohepatitis, NASH) and/or fibrosis, and may progress to cirrhosis and primary liver cancer. NAFLD is considered by many to be the hepatic manifestation of the ‘metabolic syndrome’ as it is strongly associated with obesity, type 2 diabetes, dyslipidaemia and hypertension. Initial definitions used a threshold of alcohol consumption (typically 28 units per week for men or 21 units for women) for diagnosis. However, an alternative nomenclature of metabolic (dysfunction)-associated fatty liver disease, or NAFLD, has recently been proposed to reflect our better understanding of the risk factors and to describe those patients in whom this coexists with alcohol excess.

Overall, NAFLD is estimated to have a global prevalence of 24%. A large European study found NAFLD to be present in 94% of obese patients (body mass index (BMI) > 30kg/m²), 67% of overweight patients (BMI > 25kg/m²) and 25% of normal-weight patients. The overall prevalence of NAFLD in patients with type 2 diabetes ranges from 40% to 70%. The frequency of steatosis varies with ethnicity (45% in patients of Hispanic origin, 33% in those of European ancestry and 24% in those of African ancestry) and gender (in those of European descent, 42% males vs 24% females).

Fibrosis is the main determinant of outcome. Patients with cirrhosis have a high risk of liver-related adverse outcomes, whereas those with less advanced fibrosis are more likely to have extra-hepatic cancers and vascular events. Patients with NASH have significantly higher rates of fibrosis progression than those with simple steatosis. Due to its increasing prevalence, NAFLD cirrhosis is predicted to become the main aetiology in patients undergoing liver transplantation during the next 5 years.

Pathophysiology

The initiating events in NAFLD are typically based on the development of obesity and insulin resistance, leading to increased hepatic free fatty acid flux. This imbalance between the rate of import/synthesis and the rate of export/catabolism of fatty acids in the liver leads to the development of steatosis. This may be an adaptive response through which hepatocytes store potentially toxic lipids as relatively inert triglyceride. A “two-hit” hypothesis has been proposed to describe the pathogenesis of NAFLD, the “first hit” causing steatosis that then progresses to NASH or fibrosis if a “second hit” occurs. In reality, progression probably follows hepatocellular injury caused by a combination of different “hits”, including:

- oxidative stress due to free radicals produced during fatty acid oxidation
- direct lipotoxicity from fatty acids and other metabolites in the liver
- endoplasmic reticulum stress
- gut-derived endotoxin
- cytokine release (TNF-α etc.) and immune-mediated hepatocellular injury.
Cellular damage triggers cell death and inflammation, which leads to stellate cell activation and development of hepatic fibrosis that culminates in cirrhosis (see Fig. 24.31). As with many other liver diseases, genetic and environmental factors interact to determine disease progression:

- **Genetics.** Several genetic modifiers of disease severity have been identified, with PNPLA3 and its product, adiponutrin, being the best validated.
- **Demographics.** Cirrhosis is more common with increasing age, although possibly just reflecting longer duration of disease. Higher rates of fibrosis progression are observed in men and post-menopausal women.
- **Diet.** Excessive alcohol consumption leads to increased fibrosis progression, whereas coffee consumption appears to be protective against fibrosis and HCC in NAFLD.
- **Intestinal microbiota.** Obesity, diabetes and NAFLD are all linked with gut dysbiosis, with several microbial signatures associated with advanced fibrosis. The gut microbiome may influence intestinal permeability and delivery of pathogen-associated molecular patterns (PAMPs) through the portal circulation that trigger liver inflammation.
- **Comorbidity.** The presence of type 2 diabetes and severe obesity are associated with higher rates of cirrhosis in NAFLD.

NAFLD should not be confused with acute fatty liver, which can occur in hepatic mitochondrial cytopathies, e.g. acute fatty liver of pregnancy or drug toxicity (sodium valproate, tetracyclines), or with bacterial toxins (e.g. Bacillus cereus). In these, defective mitochondrial beta-oxidation of lipids leads to fat droplet accumulation in hepatocytes and microvesicular steatosis.

**Clinical features**

NAFLD is frequently asymptomatic, although it may be associated with fatigue and mild right upper quadrant discomfort. It is commonly identified as an incidental biochemical abnormality during routine blood tests or as a fatty liver on abdominal imaging. Alternatively, patients may present late in the natural history of the disease with complications of cirrhosis and portal hypertension, such as variceal haemorrhage, or with hepatocellular carcinoma.

The average age of NAFLD cirrhosis patients is currently 50–60 years; however, the emerging epidemic of childhood obesity means that NAFLD is present in increasing numbers of younger patients. NAFLD is also associated with polycystic ovary syndrome and obstructive sleep apnoea.

**Investigations**

Investigation of patients with suspected NAFLD should aim to confirm the presence of fat in the liver and determine the extent of fibrosis. It is important to assess alcohol consumption as a contributory factor and check for medications that cause fatty liver, such as tamoxifen, amiodarone and corticosteroids. Investigations should exclude other coexisting liver diseases (including viral, autoimmune and inherited causes).

**Biochemical tests**

There is no single diagnostic blood test for NAFLD. Serum GGT is often raised. ALT and AST may be normal or modestly raised, usually less than twice the upper limit of normal. ALT levels fall as hepatic fibrosis increases and the normal AST:ALT ratio of <1 reverses as advanced fibrosis develops. Other laboratory abnormalities that may be present include low-titre antinuclear antibody (ANA) in 20%–30% of patients and elevated ferritin levels.

Although routine blood tests are unable to determine the degree of liver fibrosis accurately, several calculated scores, such as the NAFLD Fibrosis Score and FIB-4 Score, which are based on the results of routinely available blood tests and anthropometrics, have a high negative predictive value for advanced fibrosis/cirrhosis (Box 24.50). A low score can therefore be used to rule out advanced fibrosis in many NAFLD patients, allowing care to focus on those most likely to have advanced disease. Specific serum fibrosis markers such as the Enhanced Liver Fibrosis panel may also be used.

**Imaging**

Ultrasound is most often used and provides a qualitative assessment of hepatic fat content, as the liver appears “bright” due to increased echogenicity; however, sensitivity is limited when fewer than 33% of hepatocytes are steatotic. CT, MRI or MR spectroscopy offer greater sensitivity for detecting lesser degrees of steatosis, but these are resource-intensive and not widely used. No routine imaging modality can distinguish simple steatosis from steatohepatitis or accurately quantify hepatic fibrosis short of cirrhosis.

**Transient elastography**

Transient elastography (TE) is often used to assess those with indeterminate fibrosis scores. Liver stiffness can predict the likelihood of advanced fibrosis and is well validated in NAFLD, although readings may get less reliable with BMI over 40. Controlled Attenuation Parameter (CAP) is an ultrasound-based technique which can be performed simultaneously with TE to quantify steatosis non-invasively.

**Liver biopsy**

Although it is frequently not required for either diagnosis or staging, liver biopsy remains the “gold standard” investigation for diagnosis and assessment of degree of inflammation and extent of liver fibrosis. The histological changes seen in NAFLD are identical to those described in ALD (see previous section). The definition of NASH is based on a combination of three lesions (steatosis, hepatocellular injury and inflammation; see Fig. 24.31) with a mainly centrilobular, acinar zone 3 distribution. Perisinusoidal fibrosis is a characteristic feature of NAFLD. Histological scoring systems are widely used to assess both necroinflammation and fibrosis severity semi-quantitatively.

It is important to note that hepatic fat content tends to diminish as cirrhosis develops and so NAFLD is likely to be under-diagnosed in the setting of advanced liver disease, where it is thought to be the underlying cause of 30%–75% of cases in which no specific aetiology is readily identified (so-called “cryptogenic cirrhosis”).

Management
As it is a marker of the metabolic syndrome, identification of NAFLD should prompt screening for and treatment of cardiovascular risk factors in all patients. It is also necessary to assess whether patients have advanced fibrosis so that liver-targeted treatment can be focused particularly on those patients. An example of an algorithm for the assessment and risk stratification of patients with NAFLD is provided in Fig. 24.32.

Non-pharmacological treatment
Current treatment comprises lifestyle interventions to promote weight loss and improve insulin sensitivity through dietary changes and physical exercise. Sustained weight reduction of 7%–10% is associated with significant improvement in histological and biochemical NASH severity. However, this is only achieved by a small proportion of patients, focusing attention on other strategies. A Mediterranean diet pattern and reduced fructose consumption may also be helpful.

Pharmacological treatment
No pharmacological agents are currently licensed specifically for NAFLD therapy. Treatment directed at coexisting metabolic disorders, such as dyslipidaemia and hypertension, should be given. Although HMG-CoA reductase inhibitors (statins) do not ameliorate NAFLD, there does not appear to be any increased risk of hepatotoxicity or other side-effects, and so they may be used safely to treat dyslipidaemia. Specific insulin-sensitising agents, in particular glitazones, may help selected patients. Positive results with high-dose vitamin E (800 U/day) have been tempered by evidence that high doses may be associated with an increased risk of prostate cancer and all-cause mortality, which has limited its use. Obeticholic acid, a farnesoid X receptor agonist, appears to improve fibrosis in non-cirrhotic NASH in an interim analysis but the trial is ongoing. Several other new medicines are currently in late-phase clinical trials and so liver-targeted pharmacological treatments are likely to be available within the next few years.

Autoimmune liver and biliary disease

The liver is an important target for autoimmune injury. The clinical picture is dictated by the nature of the autoimmune process and, in particular, the target cell for immune injury. The disease patterns are quite distinctive for primary hepatocellular injury (autoimmune hepatitis) and biliary epithelial cell injury (primary biliary cholangitis and primary sclerosing cholangitis).

Autoimmune hepatitis
Autoimmune hepatitis (AIH) is a disease of immune-mediated injury targeting hepatocytes, which can present either as an acute severe hepatitis or chronic hepatitis leading to cirrhosis. It is a lifelong disease which often runs a relapsing and remitting course. It can develop at any age, with peaks around the second and sixth decades. It is more common in women with a 5:1 predominance. It has a strong association with other autoimmune diseases (Box 24.51).

Pathophysiology
It is characterised by the presence of serum antibodies and peripheral blood T lymphocytes reactive with self-proteins, and high levels of serum immunoglobulins – in particular, IgG. The reasons for the breakdown in immune tolerance in autoimmune hepatitis remain unclear. There are strong HLA associations (typically DR3 and DR4), indicating an underlying genetic predisposition, with a presumed environmental trigger. Exposure to the antibiotic nitrofurantoin can induce autoimmune hepatitis in a small number of cases, and cross-reactivity to viruses such as HAV and EBV has been proposed as an alternative trigger.

Clinical features
Some patients may be asymptomatic, with a raised ALT detected on blood tests. The onset of symptoms is usually insidious, with fatigue, anorexia and arthralgia. The non-specific nature of the early features can lead to the diagnosis being missed in the early disease stages. In about one-quarter of patients the onset is acute, resembling viral hepatitis, but
resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, can be present. Approximately 25% of patients will have cirrhosis at diagnosis, and some will progress to cirrhosis despite treatment.

**Investigations**

There is no single diagnostic test for autoimmune hepatitis. Liver enzymes typically show raised ALT and AST, although these fluctuate. Serological tests for autoantibodies are often positive (Box 24.52). The most frequently seen autoantibody pattern is high titre of antinuclear and/or anti-smooth muscle antibodies, typically associated with raised IgG levels, frequently seen in young adult females. Disease characterised by the presence of anti-liver–kidney microsomal (LKM) antibodies, recognising cytochrome P450-11D6 expressed on the hepatocyte membrane, is typically seen in paediatric populations and can be more resistant to treatment than ANA-positive disease. More recently, a pattern of antibody reactivity with anti-soluble liver antigen (anti-SLA) has been described typically in adult patients, often with aggressive disease and lacking autoantibodies of other specificities.

It should be noted that low titres of these antibodies occur in some healthy people and in patients with other inflammatory liver diseases. ANA also occur in connective tissue diseases and other autoimmune diseases (with an identical pattern of homogenous nuclear staining) while anti-smooth muscle antibody has been reported in infectious mononucleosis, chronic hepatitis C infection and a variety of malignant diseases.

Elevated serum IgG levels are an important diagnostic and treatment response feature if present, but the diagnosis is still possible in the presence of normal IgG levels. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed both to confirm the diagnosis before commencing long-term immunosuppression and to stage any liver fibrosis. It typically shows an abundance of lymphocytes and plasma cells around the portal tracts (portal lymphoplasmacytic hepatitis) with inflammation extending out from the edge of the portal tracts into the lobule (interface hepatitis). Scoring systems, such as the International Autoimmune Hepatitis Group (IAH-G) criteria, are useful for epidemiological study and for assessing trial eligibility but are complex for normal clinical practice.

**Management**

Treatment with glucocorticoids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone (30–40 mg/day) is given orally; the dose is then gradually reduced as the patient and LFTs improve. Budesonide may be used in non-cirrhotic patients if steroid side-effects are problematic. Maintenance therapy is usually with azathioprine (1–2 mg/kg daily), although introduction of this is often delayed by around a month to allow the liver enzymes to settle in case it causes drug-induced hepatotoxicity. Maintenance azathioprine can be used as monotherapy, or may be combined with low-dose prednisolone (ideally, below 5 mg/day). Second-line therapies are unlicensed with little long-term outcome data. However, in case series, mycophenolate mofetil (MMF) appears effective in patients who are azathioprine-intolerant, but less so in azathioprine non-responders. Similarly, tacrolimus appears helpful in refractory disease.

The aims of treatment are to achieve resolution of symptoms and to completely control inflammatory activity to prevent progressive fibrosis, especially in younger patients or those with cirrhosis. As flares may be asymptomatic but increase the risk of cirrhosis or decompensation, disease activity (indicated by rising ALT and IgG levels) should be monitored regularly. Maintenance treatment is required for at least 5 years and is often continued long term, as relapse rates are high if immunosuppression is withdrawn.

**Primary biliary cholangitis**

Primary biliary cholangitis (PBC, formerly known as primary biliary cirrhosis until 2015, when the name was changed to reflect the large proportion of non-cirrhotic patients) is a chronic, progressive cholestatic liver disease that predominantly affects women aged 30 and over. It is strongly associated with the presence of antimitochondrial antibodies (AMA), which in combination with cholestatic liver enzymes are diagnostic of PBC. It is characterised by granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This, in turn, leads to fibrosis and cirrhosis of the liver.

**Epidemiology**

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America but is rare in Africa and Asia. There is a strong female-to-male predominance of 9:1; it is also more common among cigarette smokers. Clustering of cases has been reported, suggesting an environmental trigger in susceptible individuals.

**Pathophysiology**

Immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a genetic association with HLA-DRB, together with polymorphisms in a number of other genes regulating the nature of the immune response (e.g. IL-12 and its receptor). AMA is directed at pyruvate dehydrogenase complex, a mitochondrial enzyme complex that plays a key role in cellular energy generation. PBC-specific ANAs (such as those directed at the nuclear pore antigen gp210) have a characteristic staining pattern in immunofluorescence assays (selectively binding to the nuclear rim or nuclear dots), which means that they should not be mistaken for the homogenously staining ANA seen in autoimmune hepatitis. Increases in serum immunoglobulin levels are frequent but, unlike in autoimmune hepatitis, it is typically IgM that is elevated.

Pathologically, chronic granulomatous inflammation destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis.

**Clinical features**

PBC may be detected incidentally on routine blood tests, but systemic symptoms such as fatigue and generalised itch are common. The severity of these symptoms does not correlate with the severity of the liver
disease. Although there may be right upper abdominal discomfort, the typical biliary-type pain, fever and rigors seen with bacterial cholangitis do not occur in PBC. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis. Xanthomatous deposits occur in a minority, especially around the eyes. Scratch marks may be found in patients with severe pruritus.

**Associated diseases**

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly the sicca syndrome, systemic sclerosis, coeliac disease and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

**Diagnosis and investigations**

The LFTs show a pattern of cholestasis (see Box 24.2). Hypercholesterolaemia is common and worsens as disease progresses but appears not to be associated with increased cardiovascular risk. AMA is present in over 95% of patients; when it is absent, the diagnosis should not be made without obtaining histological evidence and considering cholangiography (typically MRCP) to exclude other biliary disease. Due to the peripheral nature of the ducts affected by PBC, the biliary tree should appear normal on imaging. ANA and anti-smooth muscle antibodies are present in around 15% of patients (see Box 24.52); autoantibodies found in associated diseases may also be present. Fibrosis stage should be assessed, usually using transient elastography. Liver biopsy is necessary only if there is diagnostic uncertainty. The histological features of PBC correlate poorly with the clinical features; portal hypertension can develop before the histological onset of cirrhosis.

**Management**

The hydrophilic bile acid ursodeoxycholic acid (UDCA), at a dose of 13–15mg/kg daily, improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects; it is therefore widely used in the treatment of PBC and should be regarded as the optimal first-line treatment. Eighty percent of patients will have a good biochemical response to UDCA with a reduction in serum alkaline phosphatase to normal or near-normal levels, and this corresponds to very good long-term outcomes. However, a significant minority of patients, especially those presenting under the age of 50 years, show an inadequate response to UDCA, and have an increased risk of developing end-stage liver disease. Obeticholic acid (OCA) is a second-generation bile acid therapeutic that acts as an agonist for the nuclear farnesoid X receptor. It improves alkaline phosphatase in more than half of patients who did not respond to or tolerate UDCA, and is licensed for second-line therapy in PBC. Bezafibrate, a peroxisome proliferator-activated receptor-alpha (PPARα) agonist used predominantly to treat hyperlipidaemia, has also been shown to improve alkaline phosphatase in the majority of UDCA non-responders, although it is not licensed for this use. Due to the short-term nature of the studies, neither drug has yet been shown to alter clinically significant outcomes. Despite the autoimmune aetiology, immunosuppressants, such as glucocorticoids, azathioprine, penicillamine and ciclosporin, have all failed to show any overall benefit when given to unselected PBC patients.

Liver transplantation should be considered once liver failure has developed and may also be indicated in patients with intractable pruritus. Serum bilirubin remains the most reliable marker of declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease will recur in over one-third of patients at 10 years.

**Pruritus**

This is the main symptom requiring treatment. The cause is unknown, but up-regulation of opioid receptors and increased levels of endogenous opioids may play a role. First-line treatment is with the anion-binding resin colestyramine, which probably acts by binding potential pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16g/day orally is used. The powder is mixed in orange juice and the main dose (8g) taken before and after breakfast, when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (most obviously UDCA) and adequate spacing should be used between drugs. Colestyramine is sometimes ineffective and can be difficult for some patients to tolerate. Alternative treatments include rifampicin (150mg/day, titrated up to a maximum of 600mg/day as required with close monitoring of LFTs), naltrexone (an opioid antagonist; 25mg/day initially, increasing up to 300mg/day), plasmapheresis and a liver support device (e.g. a molecular adsorbent recirculating system, MARs).

**Fatigue**

Fatigue affects about one-third of patients with PBC. The cause is unknown but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression, hypothyroidism and coeliac disease have been excluded, there is currently no specific treatment. The impact on patients’ lives can be substantial.

**Malabsorption**

Prolonged cholestasis is associated with steatorrhoea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

**Bone disease**

Osteopenia and osteoporosis are common and normal post-menopausal bone loss is accelerated. Baseline bone density should be measured and treatment started with replacement calcium and vitamin D₃. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia is rare.

**Overlap syndromes**

**AMA-negative PBC (‘autoimmune cholangitis’)**

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable AMA in the serum. Serum transaminases, serum immunoglobulin levels and titres of ANA tend to be higher than in AMA-positive PBC. The clinical course mirrors classical PBC, however, and these patients should be considered as having a variant of PBC.

**PBC/autoimmune hepatitis overlap**

A few patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulin IgG levels and interface hepatitis on liver histology. In such individuals, a trial of glucocorticoid therapy may be beneficial.

**Primary sclerosing cholangitis**

Primary sclerosing cholangitis (PSC) is an immune-mediated cholestatic liver disease characterised by multifocal strictureing of the larger bile ducts of the extra- and/or intrahepatic biliary tree, often in association with inflammatory bowel disease. This is also associated with progressive hepatic fibrosis which can lead to cirrhosis and portal hypertension, along with an increased risk of various cancers (cholangiocarcinoma, gallbladder, colon).

The incidence is about 6.3/100000 in people of European ancestry. Unlike most other autoimmune diseases, PSC is twice as common in men as women. Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography
- absence of choledocholithiasis (or history of bile duct surgery)
- exclusion of bile duct cancer, by prolonged follow-up.
The term ‘secondary sclerosing cholangitis’ is used to describe the typical changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in Box 24.53.

Pathophysiology

The cause of PSC is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis (Box 24.54). About 70%–80% of PSC patients have coexisting ulcerative colitis, and PSC is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop PSC, particularly those with extensive colitis or pancolitis. The distribution of PSC-associated colitis is often predominantly right-sided with relative distal sparing, and may be less symptomatic that non-PSC IBD. The prevalence of PSC is lower in patients with Crohn’s colitis (about 1%). Patients with PSC and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and individuals who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

PSC is thought to be an immunologically mediated disease, triggered in genetically susceptible individuals by toxic or infectious agents, which may gain access to the biliary tract through a leaky, diseased colon. A close link has been identified with HLA haplotype A1-B8-DR3-DW52A, which is commonly found in association with other organ-specific autoimmune diseases (e.g., autoimmune hepatitis).

Perinuclear antineutrophil cytoplasmic antibodies (ANCA) have been detected in the sera of 60%–80% of patients with PSC with or without ulcerative colitis, and in 30%–40% of patients with ulcerative colitis alone. The antibody is not specific for PSC and is found in other chronic liver diseases (e.g., 50% of patients with autoimmune hepatitis), so is of little diagnostic use on its own.

Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Patients may present with episodes of biliary obstruction, or with symptoms of cirrhosis or portal hypertension. Common symptoms include fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation.

Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found at a late stage only. In addition to ANCA, low titres of serum ANA and anti-smooth muscle antibodies may be found in PSC but have no diagnostic significance; serum AMA is absent.

The key investigation is MRCP, which is usually diagnostic and reveals multiple irregular stricturing and dilatation (see Fig. 24.33). ERCP should be reserved for therapeutic interventions.

On liver biopsy, the characteristic early features of PSC are periductal ‘onion skin’ fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts (Fig. 24.34). Later, fibrosis spreads, progressing inevitably to biliary cirrhosis; obliteratorative cholangitis leads to the so-called ‘vanishing bile duct syndrome’.

The link with IBD and associated colon cancer risk is sufficiently strong that all patients diagnosed with PSC should undergo an initial colonoscopy, even in the absence of bowel symptoms.

Management

There is no cure for PSC but management of cholestasis and its complications and specific treatment of the disease process are indicated. UDCA is widely used, although the evidence to support this is limited. UDCA may have benefit in terms of reducing colon carcinoma risk.

The course of PSC is variable. Overall, the median time from diagnosis to death or transplant is around 20 years. Prognosis is worse in:

- Risk factors for poor outcome include age >60 years, severe fibrosis or cirrhosis, and extrapancreatic stricturing.

- Liver transplantation is the best treatment option for patients with end-stage disease.
symptomatic patients, possibly reflecting a later disease stage at diagnosis. In recent series, the leading cause of death in PSC is cholangiocarcinoma (58% of deaths), with lower rates attributable to liver failure (30%) and variceal bleeding (9%). Immunosuppressive agents, including prednisolone, azathioprine, methotrexate and ciclosporin, have been tried; results have generally been disappointing.

Symptomatic patients often have pruritus. Management is as for PBC. Fatigue appears to be less prominent than in PBC, although it is still present in some patients.

Cancer screening

Patients with PSC should have annual ultrasound scans to assess for gallbladder polyps, to aid early detection of gallbladder cancer. Patients with PSC and colitis should undergo annual colonoscopy to screen for colorectal cancer. There is not an established role for routine screening for cholangiocarcinoma with either imaging or serum CA19-9 levels, due to both the low specificity and the low likelihood of successful intervention, even with earlier diagnosis.

Management of complications

Broad-spectrum antibiotics (e.g. ciprofloxacin) should be given for acute attacks of cholangitis. If new symptoms or worsening liver tests, non-invasive imaging such as MRCP and/or contrast CT should be performed to assess for a dominant stricture (which may be either inflammatory or malignant). If a dominant stricture is associated with either jaundice or infection, ERC may be performed for sampling (via brush cytology) to exclude cholangiocarcinoma and to relieve the obstruction, usually through balloon dilatation rather than stenting. Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that requires treatment.

Surgical treatment

Surgical resection of the extrahepatic bile duct and biliary reconstruction have a limited role in the management of non-cirrhotic patients with dominant extrahepatic disease. Orthotopic transplantation is the only surgical option in patients with advanced liver disease; 5-year survival is 80%–90% in most centres. Unfortunately, the condition may recur in the graft in around 20% of patients and there are no identified therapies able to prevent this. Cholangiocarcinoma is a contraindication to transplantation. Colon carcinoma risk persists following transplantation (and may be increased because of immunosuppression) so colonoscopic surveillance should continue.

A comparison of PBC and PSC is shown in Box 24.53.

IgG4-associated cholangitis

This disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in more than 90% of the patients), IgG4-associated cholangitis (IAC) often presents in middle-aged to older men with obstructive jaundice (due to either hilar stricturing/intrahepatic sclerosing cholangitis or a low bile duct stricture). Cholangiographic appearances can resemble PSC or hilar cholangiocarcinoma. Patients may have past or concurrent evidence of IgG4 disease in other organs (Box 24.55). The serum IgG4 is often raised and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. It is important not to miss the diagnosis as it responds well to glucocorticoid therapy, often with complete normalization of liver enzymes and resolution of strictures on serial imaging.

Liver tumours and other focal liver lesions

Identification of a hepatic mass lesion is common, both in patients with known pre-existing liver disease and as a primary presentation. Although primary and secondary malignant tumours are important potential diagnoses, benign disease is frequent. The critical steps to be taken in diagnosing hepatic mass lesions are:

- determining the presence, nature and severity of any underlying chronic liver disease, as the differential diagnosis is very different in patients with and those without chronic liver disease
- using optimal (usually multiple) imaging modalities.

Primary malignant tumours

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the most common primary liver tumour, and the sixth most frequent cause of cancer worldwide. Cirrhosis is present in 75%–90% of individuals with HCC and is an important risk factor for the disease. The risk is between 1% and 5% in cirrhosis caused by hepatitis B and C. There is also an increased risk in cirrhosis due to haemochromatosis, alcohol, NAFLD and alpha-1-antitrypsin deficiency. In northern Europe, 90% of those with HCC have underlying cirrhosis, compared with 30% in Taiwan, where hepatitis B is the main risk factor. The age-adjusted incidence rates vary from 28 per 100 000 in South-East Asia (reflecting the prevalence of hepatitis B) to 10 per 100 000 in southern Europe and 5 per 100 000 in northern Europe. Chronic hepatitis B infection increases the risk of HCC 100-fold and is the major risk factor worldwide. The risk of HCC is 0.4% per year in the absence of cirrhosis and 2%–6% in cirrhosis. The risk is four times higher in HBeAg-positive individuals than in those who are HBeAg-negative. Hepatitis B vaccination has led to a fall in HCC in countries with a high prevalence of hepatitis B. The incidence in Europe and North America has risen recently, probably related to the increased prevalence of hepatitis C and NAFLD cirrhosis. The risk is higher in men and rises with age.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single nodule or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, while lung and bone metastases are rare. Well-differentiated tumours can resemble normal hepatocytes and can be difficult to distinguish from normal liver.
Clinical features

HCC may present with symptoms or through screening of high-risk patients. Commonly, liver function deteriorates in those with underlying cirrhosis, with worsening ascites, jaundice or variceal haemorrhage. Other symptoms can include weight loss, anorexia and abdominal pain. This often rapid deterioration may be the first presentation of previously undiagnosed cirrhosis. Examination may reveal hepatomegaly or a right hypochondrial mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur. The advanced nature of disease that presents in this way makes curative therapy unlikely.

HCC found through screening is typically detected much earlier in its natural history, significantly increasing the treatment options.

Investigations

Serum markers

Alpha-fetoprotein (AFP) is produced by 60% of HCCs. Levels increase with the size of the tumour and are often normal or only minimally elevated in small tumours detected by ultrasound screening. Serum AFP can also rise in the presence of active hepatitis B and C viral replication; very high levels are seen following acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to be interpreted with caution. Nevertheless, in the absence of active liver inflammation, a significantly elevated or progressively rising AFP warrants an aggressive search for HCC (normal range is < 10 ng/ml [IU/ml]). In HCC patients with elevated AFP levels, serial measurements can be a useful biomarker of disease progression or response to treatment.

Imaging

Ultrasound will detect focal liver lesions as small as 1 cm. The use of ultrasound contrast agents has increased sensitivity and specificity but is highly user-dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. The diagnosis is usually confirmed on either multi-phase contrast-enhanced CT or MRI, which demonstrate the typical hallmarks of HCC: arterial enhancement with washout on the portal venous phase (Fig. 24.35). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. A combination of imaging modalities (CT and MRI) may be required for indeterminate or probable HCC when the typical radiological features are absent (Fig. 24.36).

Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided in patients who may be eligible for transplantation or surgical resection because there is a small (1.8%-4%) risk of tumour seeding along the needle tract. In all cases of potential HCC where biopsy is being considered, the impact that a confirmed diagnosis will have on therapy must be weighed against the risks of bleeding.

Role of screening

Screening for HCC, by ultrasound scanning, with or without AFP measurements, every 6 months is indicated in high-risk patients who would be suitable for therapy if diagnosed with HCC. The risk is highest in patients with chronic hepatitis B and cirrhosis due to viral hepatitis and haemochromatosis, and lower in patients with cirrhosis due to Wilson’s disease and autoimmune hepatitis. Cost-effectiveness studies suggest that HCC surveillance is warranted in cirrhotic patients where there is an annual incidence of HCC of ≥ 1.5% per year. Screening may also be indicated in those with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although many studies investigating the efficacy of HCC surveillance are affected by lead-time and length-time bias, the current evidence base supports the continued use of HCC surveillance. Screening identifies smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation.

Management

This is different for patients with cirrhosis and those without. In the presence of cirrhosis, treatment options depend on tumour size and number, severity of liver disease (Child–Pugh score) and performance status. An algorithm for managing those with cirrhosis is shown in Fig. 24.36.

Hepatic resection

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. There is a 50% recurrence rate at 5 years, however, which may be due to a second de novo tumour or recurrence of the original tumour. Few patients with cirrhosis are suitable for hepatic resection because of the high risk of hepatic failure. Nevertheless, surgery can be safely performed in cirrhotic patients with small tumours, good liver function (Child–Pugh A) and the absence of clinically relevant portal hypertension (HVPG < 10 mmHg). In experienced centres, advances in surgical technique and pre-operative assessment have permitted liver resection to be performed safely in selected patients with more advanced liver disease and tumour burden.

Liver transplantation

Transplantation has the benefit of curing underlying cirrhosis and removing the risk of a second, de novo tumour in an at-risk patient. The requirement for immunosuppression creates its own risks of reactivation,
Liver tumours and other focal liver lesions

Hepatocellular carcinoma in cirrhotic liver

**Prognostic stage**

- Very early stage (0)

**Fig. 24.36 Management of hepatocellular carcinoma complicating cirrhosis.** Modified Barcelona Clinic Liver Cancer (BCLC) staging system. Patient management is determined by the size and number of tumours, evidence of portal invasion or extrahepatic spread, severity of underlying liver cirrhosis and performance status. Preserved liver function refers to Child-Pugh A cirrhosis without ascites. Performance status (PS): 0 = fully active; no symptoms; >2 = limited self-care, confined to bed or chair for more than 50% of waking hours. Optimal surgical candidate refers to a global assessment of a patient’s suitability based on compensated liver disease (Child-Pugh A), acceptable grade of portal hypertension, acceptable amount of remaining parenchyma and possibility of using a laparoscopic or minimally invasive approach.

In some countries, including the United Kingdom, transplant may be considered in patients with up to five tumours, each less than 3 cm. (HCC = hepatocellular carcinoma;

however, if residual or metastatic disease is present, and assessment of patients for suitability for liver transplantation focuses on the exclusion of extrahepatic disease and vascular invasion. The 5-year survival following liver transplantation is 75% for patients with single tumours of less than 5 cm in size or three tumours smaller than 3 cm (the Milan criteria). Extended criteria have been developed in a number of countries, including the UK, allowing patients to be transplanted with a greater number of small tumours (<5) or larger single tumours (5–7 cm) that have demonstrated stability after a period of observation (6 months), either with or without locoregional therapy.

**Ablative therapy**

Ablative therapies use a number of different techniques to achieve localised destruction of tumour tissue. US or CT-guided thermal ablative techniques, including radiofrequency ablation (RFA) and microwave ablation, have largely replaced percutaneous ethanol injection in the treatment of HCC. Alternative techniques include cryoablation and irreversible electroporation. Loco-regional ablative therapies may be curative for patients with early HCC. Thermal ablation in single tumours <3 cm in size is an alternative to surgery based on technical factors (position of the tumour), severity of underlying liver disease and comorbidity.

**Transarterial chemoembolisation**

Transarterial chemoembolisation (TACE) is the most widely used palliative treatment for patients with HCC not amenable to surgery or potentially curative ablative techniques. TACE involves the selective intra-arterial infusion of chemotherapeutic agents followed by embolisation of the tumour feeding vessels with absorbable gelatin powder (Gelfoam) to achieve localised tumour necrosis and devascularisation. Conventional TACE achieves response rates of 52% with 1-year and 3-year survival rates of 70% and 40%, respectively. Modifications of this technique include the use of drug-eluting beads. TACE should not be used in patients with advanced liver or renal dysfunction, vascular invasion or extra-hepatic spread. TACE is widely used as a bridging therapy for patients awaiting liver transplant and increasingly has found a role in down-staging therapy in patients being considered for liver transplant. Selective internal radiation therapy (SIRT) involves intra-arterial infusion of radioactive substances or microspheres into the hepatic artery. Its use is being investigated as an alternative to TACE or systemic therapy and as a bridging therapy to liver transplant.

**Systemic therapy**

Sorafenib improves survival from 8 to 11 months in cirrhotic patients, but often with significant side-effects. The drug is a multi-kinase inhibitor with activity against Raf, vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) signalling, and is the first systemic therapy to prolong survival in HCC. Levantinib is an alternative oral multi-kinase inhibitor that has demonstrated non-inferiority to sorafenib but with a different side-effect profile. Second-line therapies include regorafenib and cabozantinib. Trials of immune therapy are
ongoing. Pre-treatment with sorafenib 2–3 weeks before TACE appears to improve progression-free survival, as reported in the TACTICS trial.

### Fibrolamellar hepatocellular carcinoma

This rare variant differs from HCC in that it occurs in young adults, equally in males and females, in the absence of hepatitis B infection and cirrhosis. The tumours are often large at presentation and the AFP is usually normal. Histology of the tumour reveals malignant hepatocytes surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. This variant of HCC has a better prognosis following surgery than an equivalent-sized HCC, two-thirds of patients surviving beyond 5 years.

### Other primary malignant tumours

These are rare but include haemangio-endothelial sarcomas. Cholangiocarcinoma ( bile duct cancer) typically presents with bile duct obstruction rather than as a hepatic mass lesion, although intra-hepatic cholangiocarcinoma can present as a focal liver tumour.

### Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

#### Clinical features

The primary neoplasm is asymptomatic in 50% of patients, being detected on either radiological, endoscopic or blood biochemistry screening. There is liver enlargement and weight loss; jaundice may be present.

#### Investigations

A raised ALP activity is the most common biochemical abnormality but LFTs may be normal. Ascitic fluid, if present, has a high protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging shows filling defects (Fig. 24.37); laparoscopy may reveal the tumour and facilitates liver biopsy.

#### Management

Hepatic resection can improve survival for slow-growing colonic carcinoma metastases, and is an approach that should be actively explored in patients who are fit for liver resection and have had the primary tumour resected, once extrahepatic disease has been excluded. Patients with neuro-endocrine tumours (NETs), such as gastrinomas, insulinomas and glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients.

### Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

### Hepatic adenomas

These are common benign hepatocellular tumours that may present as an abdominal mass or with abdominal pain but now more typically present as an incidental finding on imaging. They are more common in women (female: male ratio 10:1) and are associated with oral contraceptive, androgen and anabolic steroid use. Hepatic adenomas can increase in size during pregnancy. Large or rapidly growing adenomas can rarely rupture, causing intraperitoneal bleeding. In women, resection is indicated for hepatic adenomas ≥5 cm in diameter or with exophytic protrusion, as this is associated with higher rates of bleeding. Hepatic adenomas <5 cm rarely bleed and there is a low rate of malignant transformation. Management involves avoidance of the oral contraceptive pill and weight loss. Resection is recommended for hepatic adenoma in men, irrespective of size because of a higher rate of malignant transformation.

### Haemangiomomas

These are the most common benign liver tumours and are present in 1%–20% of the population. Most are smaller than 3 cm and rarely cause symptoms. The diagnosis is usually made by ultrasound but CT/MRI may show a low-density lesion with delayed arterial filling. Surgery is needed only for very large symptomatic lesions or where the diagnosis is in doubt.

### Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is a benign polycystic hepatocellular proliferation resulting from an arterial malformation. FNH is more common in women (female: male ratio 9:1) and typically present between 35 and 50 years. Most are solitary and <5 cm but 20%–30% are multiple. The lesions are usually asymptomatic. They can be differentiated from adenoma by a focal central scar seen on CT or MRI (Fig. 24.38). Histologically, they consist of nodular regeneration of hepatocytes without fibrosis. In the absence of symptoms, surgical resection is not required. If a confident diagnosis of FNH can be made then follow-up imaging is not required. There is no need to discontinue the oral contraceptive pill or monitor in pregnancy.

### Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 24.39). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, percutaneous or surgical debulking can be attempted but recurrence is typical. Liver transplant may rarely be required in severe cases. Liver abscesses are discussed on page 891.

### Drugs and the liver

The liver is the primary site of drug metabolism and an important target for drug-induced injury. Pre-existing liver disease may affect the capacity of the liver to metabolise drugs and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses. **Box 24.56**
Drug toxicity should always be considered in the differential diagnosis of patients presenting with acute liver failure, jaundice or abnormal liver biochemistry. Drug-induced liver injury (DILI) can be classified as either intrinsic (predictable dose-related toxicity occurring in a large proportion of individuals exposed to a drug) or idiosyncratic (occurring unpredictably in a small proportion of patients exposed to a drug). Typical patterns of drug toxicity are listed in Box 24.57; the most common picture is a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to normalise following a drug-induced hepatitis, and it may be months before they normalise after a cholestatic hepatitis. Occasionally, permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

The key to diagnosis is a detailed drug history (Box 24.58), looking for temporal relationships between drug exposure and onset of liver abnormality (bearing in mind the fact that liver injury can frequently take weeks or even months to develop following exposure). A liver biopsy should be considered if there is suspicion of pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Where drug-induced liver injury is suspected or cannot be excluded, the potential culprit drug should be discontinued unless it is impossible to do so safely.

### Types of liver injury

Different histological patterns of liver injury may occur with drug injury.
**Cholestasis**

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was common when high concentrations of oestrogens (50µg/day) were used as contraceptives. Both the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canacicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic steroids used by body-builders may also cause a cholestatic hepatitis. In some cases (e.g. NSAIDs and cyclo-oxygenase 2 (COX-2) inhibitors), there is overlap with acute hepatocellular injury.

**Hepatocyte necrosis**

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granulomas may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies, including germander, comfrey and jin bu huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

**Steatosis**

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate. Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone toxicity can produce a similar histological picture to NASH.

**Vascular/sinusoidal lesions**

Drugs such as the alkylation agents used in oncology can damage the vascular endothelium and lead to hepatic venous outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

**Hepatic fibrosis**

Most drugs cause reversible liver injury and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

**Autoimmune hepatitis-like**

Nitrofurantoin is a commonly used antibiotic for urinary tract infections which can cause a liver injury with the features of autoimmune hepatitis, with raised ALT and IgG levels and anti-nuclear or anti-smooth muscle antibodies. Immune checkpoint inhibitors (such as nivolumab and pembrolizumab) are increasingly used as immunotherapy in cancer treatments. A well-recognised side-effect is the development of florid organ-specific autoimmune disease, including an autoimmune hepatitis which can require high-dose steroids to control it.

---

### Inherited liver diseases

The inherited diseases are an important and probably under-diagnosed group of liver diseases. In addition to the ‘classical’ conditions, such as haemochromatosis and Wilson’s disease, the important role played by the liver in the expression of the inborn errors of metabolism should be remembered, as should the potential for genetic underpinning for intrahepatic cholestasis.

---

### Haemochromatosis

Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 24.59).

### Genetic haemochromatosis

In genetic haemochromatosis (GH), iron is deposited throughout the body and total body iron may reach 20–60g (normally 4g). The important organs involved are the liver, pancreatic islets, endocrine glands, joints and heart. In the liver, iron deposition occurs first in the perportal hepatocytes, extending later to all hepatocytes, with associated fibrosis and eventually cirrhosis.

**Pathophysiology**

Body iron content is controlled by regulation of iron absorption from diet and its storage in the reticuloendothelial system. The hormone hepcidin inhibits iron transport by binding to ferroportin on enterocytes and macrophages (see Fig. 25.20). Approximately 90% of GH patients are homozygous for a single point mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein, which leads to reduced hepcidin levels and ultimately, uncontrolled increased iron absorption. This is one of the most frequent genetic disorders in Northern European populations. However, penetrance is variable and fewer than 50% of C282Y homozygotes will develop clinical features of haemochromatosis. Iron loss in menstruation and pregnancy can delay the onset of GH in females. A single copy of the C282Y mutation can also cause GH if also accompanied by a histidine-to-aspartic acid mutation at position 63 (H63D), referred to as compound heterozygosity. This genotype has a lower risk of iron overload and typically causes a less severe form of haemochromatosis. A number of other rare autosomal recessive mutations leading to GH are described. The second most common form of inherited iron disorder is ferroportin disease, an autosomal dominant disorder which typically has a milder clinical phenotype than HFE-associated haemochromatosis.

**Clinical features**

Symptomatic disease usually presents in men over 40 years of age with features of liver disease (often with hepatomegaly), diabetes or heart failure. Fatigue and arthropathy are early symptoms but are frequently absent. Leaden-grey skin pigmentation can sometimes occur due to excess melanin, especially in exposed parts, axillae, groins and genitalia: hence the term ‘bronzed diabetes’. Impotence, loss of libido and testicular atrophy are recognised complications, as are early-onset osteoarthritis targeting unusual sites such as the metacarpophalangeal joints, chondrocalcinosis and pseudogout. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.
alcohol-related cirrhosis, are associated with widespread secondary iron overload. The features are similar to those of primary haemochromatosis but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for HFE mutations and this may contribute to the development of iron overload.

**Wilson's disease**

Wilson's disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism caused by a variety of mutations in the ATP7B gene. Pathological copper accumulation leads to damage to liver, brain and other organs.

**Pathophysiology**

Copper acts as a cofactor for a number of essential enzymes. Dietary absorption is usually balanced by excretion into bile. The ATP7B gene encodes a transmembrane copper-transporting ATPase which excretes copper into bile, and loss of function causes excessive copper accumulation. This transporter is also required for synthesis of functional caeruloplasmin, the circulating copper-binding protein. The amount of copper in the body at birth is normal but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

At least 700 different mutations have been described. Most cases are compound heterozygotes with two different mutations in ATP7B. Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns. The large number of culprit mutations means that, in contrast to haemochromatosis, genetic diagnosis is not routine in Wilson's disease, although it may have a role in screening families following identification of the genotype in an index patient.

**Clinical features**

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence. Neurological damage causes movement disorders and dementia, which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

**Liver disease**

There is a wide spectrum of acute and chronic presentations of liver disease, including asymptomatic elevated liver enzymes, acute hepatitis, recurrent jaundice and silent progression to cirrhosis. Fulminant liver failure can occur, especially in young women. This causes the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. The possibility of Wilson's disease should be considered in any patient under the age of 40 presenting with recurrent acute hepatitis or chronic liver disease of unknown cause, especially when this is accompanied by haemolytic anaemia.

**Neurological disease**

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia. Neurological disease typically develops after the onset of liver disease and can be prevented by effective treatment. This increases the importance of diagnosis in the liver phase beyond just allowing effective management of liver disease.

**Kayser–Fleischer rings**

These constitute the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson's disease (less often in children but almost always in neurological Wilson's disease), but require slit-lamp examination for correct identification. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery. They disappear with treatment.
Investigations

Diagnosis of Wilson’s disease is based on algorithms incorporating symptoms and signs, measures of copper metabolism and DNA analysis. A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. However, advanced liver failure from any cause can also reduce the serum caeruloplasmin, and conversely a normal value does not exclude the diagnosis if there is a high index of suspicion. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than 0.6 µmol/24 hrs (38 µg/24 hrs) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion while giving D-penicillamine is a useful confirmatory test; more than 25 µmol/24 hrs is considered diagnostic of Wilson’s disease.

Management

Pharmacological treatment is with either chelating-agents (D-penicillamine or trientine) that increase urinary copper excretion, or zinc salts, which reduce absorption of dietary copper. The copper-binding agent penicillamine is the drug of choice. The dose given must be sufficient to produce cupriuresis and most patients require 1.5 µg/day (range 1–4 µg). The dose can be reduced once the disease is in remission but treatment must continue for life, even through pregnancy. Care must be taken to ensure that re-accumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these arise, trientine dihydrochloride (1.2–2.4 µg/day) and zinc (50 mg/3 times daily) are potential alternatives.

Prognosis is excellent with early treatment, and presymptomatic patients compliant with treatment have comparable survival to the general population. Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson’s disease is unclear. Siblings and children must be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

Alpha-1-antitrypsin deficiency

Alpha-1-antitrypsin (α1-AT) is a serine protease inhibitor (Serpin, or Pi) produced by the liver and secreted into the circulation. One of its main functions is the breakdown of neutrophil elastase. Circulating levels of α1-AT can double during the acute phase response and play a key anti-inflammatory role, preventing damage to normal tissue. Numerous variants of the SERPINA1 gene have been described but there are two common mutations. The wild type is known as the M allele. Ninety-five percent of cases of severe deficiency are due to homozygosity of the Z allele. Mild deficiency can result from the less-severe S allele. The mutated α1-AT forms polymers within the endoplasmic reticulum of hepatocytes, with reduced secretion into the blood. The accumulation of polymers within hepatocytes causes the liver toxicity, whereas the unopposed neutrophil elastase activity causes damage to structural proteins in the lungs. Homozygous individuals (PiZZ) have low plasma α1-AT concentrations, although globules containing α1-AT are found in the liver, and these people may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously; and chronic hepatitis leading to cirrhosis in adults. Alpha-1-AT deficiency is an exacerbating factor for liver disease of other aetiologies, and the possibility of dual pathology should be considered when severity of disease, such as ALD, appears disproportionate to the level of underlying insult.

There are no clinical features that distinguish liver disease due to α1-AT deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma α1-AT concentration and genotyping for the presence of the mutation. Alpha-1-AT-containing globules can be demonstrated in the liver (Fig. 24.41) but this is not necessary to make the diagnosis.

Gilbert syndrome

Gilbert syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 24.12). It is an autosomal recessive trait caused by a mutation in the promoter region of the gene for UDP-glucuronoyl transferase enzyme (UGT1A1), which leads to reduced enzyme expression. It can be inherited in a dominant fashion when there is a missense mutation in the gene. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronoyl transferase.

Clinical features

The typical presentation is with isolated elevation of bilirubin, typically, although not exclusively, in the setting of physical stress or illness. There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence stercobilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed. In the presence of haemolysis, pallor due to anaemia and splenomegaly due to excessive reticuloendothelial activity are usually present.

Investigations

The plasma bilirubin is usually less than 100 µmol/L (6 mg/dL) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Hepatic histology is normal and liver biopsy is not recommended for the investigation of patients with possible Gilbert syndrome. The condition is not associated with liver injury and thus has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.

Vascular liver disease

Metabolically, the liver is highly active and has large oxygen requirements. This places it at risk of ischaemic injury in settings of impaired perfusion. The risk is mitigated, however, by the dual perfusion of the liver (via the portal vein as well as hepatic arteries), with the former representing a low-pressure perfusion system that offers protection against the potential effects of arterial hypotension. The single outflow through the hepatic vein and the low-pressure perfusion system of the portal vein make the liver vulnerable to venous thrombotic ischaemia in the context of Budd-Chiari syndrome and portal vein thrombosis, respectively.
Hepatic arterial disease

Liver ischaemia

Liver ischaemic injury (ischaemic hepatitis) is relatively common during hypotensive or hypoxic events and is under-diagnosed. The characteristic pattern is one of rising transaminase values in the days following such an event (e.g. prolonged seizures). Ischaemic hepatitis is more common in patients with pre-existing hepatic congestion (e.g. congestive cardiac failure) or underlying liver disease. Liver synthetic dysfunction and encephalopathy are uncommon but can occur. Liver failure is very rare. Diagnosis typically rests on clinical suspicion and exclusion of other potential aetiologies. Treatment is aimed at optimising liver perfusion and oxygen delivery. Outcome is dictated by the morbidity and mortality associated with the underlying disease, given that liver ischaemia frequently occurs in the context of other organ ischaemia in high-risk patients.

Liver arterial disease

Hepatic arterial disease is rare outside the setting of liver transplantation and is difficult to diagnose. It can cause significant liver damage. Hepatic artery occlusion may result from inadvertently injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually >1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic artery aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis and surgical or biopsy trauma are the main causes. They usually lead to bleeding into the biliary tree, peritoneum or intestine. CT scans are helpful in identifying the location of the aneurysm, adjacent structures and evidence of rupture. Angiography remains the gold standard for diagnosis. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery but this rarely causes symptoms.

Hepatic artery thrombosis (HAT) is a recognised complication of liver transplantation and typically occurs in the early post-transplant period. Clinical features are often related to bile duct rather than liver ischaemia because of the dominant role of the hepatic artery in extrahepatic bile duct perfusion. Manifestations can include bile duct anastomotic failure with bile leak or the development of late bile duct strictures (ischaemic cholangiopathy). Diagnosis and initial intervention are radiological in the first instance, with ERCP and biliary stenting being the principal approaches to the treatment of biliary strictures causing significant cholestasis.

Portal venous disease

Portal hypertension

See page 881.

Portal vein thrombosis

Portal venous thrombosis as a primary event is rare but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may rarely lead to bowel infarction, requiring surgery. Underlying thrombophilia needs to be excluded. Treatment is based on anticoagulation, which is associated with increased recanalisation rates following acute portal vein thrombosis. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension. Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low.

Portal vein thrombosis can arise as a secondary event in patients with cirrhosis and portal hypertension, and is a recognised cause of decompensation in patients with previously stable cirrhosis. In individuals showing such decompensation, portal venous patency should be assessed by ultrasound with Doppler flow studies. The role of anticoagulation in patients with chronic portal vein thrombosis is unclear, but it is recommended in potential transplant candidates to reduce the risk of clot propagation. Chronic portal vein thrombosis can be a cause of portal hypertension.

Hepatopulmonary syndrome

This condition is characterised by resistant hypoxaemia ($\text{PaO}_2 < 9.3\,\text{kPa}$ (70 mmHg)), intrapulmonary vascular dilatation in patients with cirrhosis, and portal hypertension. Clinical features include finger clubbing, cyanosis and a characteristic reduction in arterial oxygen saturation on standing (orthodeoxia). The hypoxia is due to intrapulmonary shunting through direct arteriovenous communications. Nitric oxide (NO) over-production may be important in pathogenesis. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe ($\text{PaO}_2 < 6.7\,\text{kPa}$ (50 mmHg)), is associated with an increased operative risk.

Portopulmonary hypertension

This unusual complication of portal hypertension is similar to ‘primary pulmonary hypertension’ (p. 549). It is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. The condition is caused by vasocostriction and obliteration of the pulmonary arterial system and leads to breathlessness and fatigue.

Hepatic venous disease

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart. The clinical features depend on the cause and on the speed with which obstruction develops, and can mimic many other forms of chronic liver disease, sometimes leading to delayed diagnosis. Congestive hepatomegaly and ascites are the most consistent features. The possibility of hepatic venous obstruction should always be considered in patients with an atypical liver presentation.

Budd–Chiari syndrome

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Many patients have haematological disorders such as myelofibrosis, primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria, or antithrombin III, protein C or protein S deficiencies (Ch. 25). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena cava stenosis are the other main causes. The underlying cause cannot be found in about 30% of patients, although this percentage is falling as molecular diagnostic tools (e.g. for the JAK2 mutation in myelofibrosis) increase the capacity to diagnose underlying haematological disorders. Hepatic congestion affecting the centrilobular areas is followed by centrilobular fibrosis, and eventually cirrhosis supervenes in those who survive long enough.

Clinical features

Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and, often, upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.
Investigations
The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis. Ascitic fluid analysis shows a protein concentration above 25g/L (2.5g/dL) (exudate) in the early stages; however, this often falls later in the disease. Doppler ultrasound may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as this often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is needed only if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

Management
Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, thrombolysis with recombinant tissue plasminogen activator or streptokinase, followed by heparin and oral anticoagulation, should be considered. Long-term anticoagulation is required. Ascites is initially treated medically but often with only limited success. Short hepatic venous strictures can be treated with angioplasty. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPS, followed by anticoagulation. Surgical shunts, such as portacaval shunts, are rarely performed now that TIPS is available. Approximately 40% of patients will require TIPS following failure of medical management. Survival at 1 year and 5 years following TIPS is 88% and 78%, respectively. Occasionally, a web can be resected or an inferior vena cava stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

Sinusoidal obstruction syndrome (veno-occlusive disease)
Sinusoidal obstruction syndrome (SOS, previously known as veno-occlusive disease) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in Senecio and Heliotropium plants used to make teas, as well as cytotoxic drugs and hepatic irradiation, are all recognised causes. SOS may develop in 10%–20% of patients following haematopoietic stem cell transplantation (usually within the first 20 days) and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting, SOS is thought to relate to pre-conditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous outflow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may facilitate the diagnosis. Treatment involves close supportive care/fluid management to maintain intravascular filling, and in severe cases, defibrotide, a drug that binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation, is recommended.

Cardiac disease
Hepatic damage, due primarily to congestion, may develop in all forms of right heart failure: usually, the clinical features are predominantly cardiac. Very rarely, long-standing cardiac failure and hepatic congestion give rise to cardiac cirrhosis. Liver cirrhosis is a recognised complication of some forms of congenital heart disease. Fontan-associated liver disease develops in patients with diverse forms of congenital cardiac disease resulting in a single functioning ventricle, treated with the Fontan procedure. Chronic hepatic congestion resulting from passive filling of the pulmonary arterial circulation results in progressive liver fibrosis and cirrhosis. Severe left ventricular dysfunction is a cause of ischaemic hepatitis. Cardiac causes of acute and chronic liver disease are typically under-diagnosed. Treatment is principally that of the underlying heart disease with supportive treatment for the liver component.

Nodular regenerative hyperplasia of the liver
This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. It is believed to be due to damage to small hepatic arteries and portal venules. It occurs in older people and is associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs, such as azathioprine. The condition is usually asymptomatic but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis is very favourable. Management is based on treatment of the portal hypertension.

Pregnancy and the liver
The inter-relationship between liver disease and pregnancy can be a complex one and a source of real anxiety for both the patient and the clinician. Three possibilities need to be borne in mind when treating a pregnant woman with a liver abnormality:

- This represents a worsening of pre-existing chronic liver or biliary disease (although pregnancy may be the first time a woman’s liver biochemistry has been tested, so this may not have previously been diagnosed).
- This represents a genuine first presentation of liver disease that is not intrinsically related to pregnancy.
- This represents a genuine pregnancy-associated liver injury process.

It is critical to obtain information relating to liver disease risk factors and pre-pregnancy liver status to establish whether any abnormality was present before pregnancy. In general, the earlier in pregnancy that liver abnormality presents, the more likely it is to represent either pre-existing liver disease or non-pregnancy-related acute liver disease. Equally, the best outcome for both mother and baby results from optimising the physical condition of the mother, and in situations of deteriorating liver function (which can be steep in late pregnancy) consideration should always be given to early delivery if the fetus is viable. Joint management between hepatologists and obstetricians is essential.

Intercurrent and pre-existing liver disease
Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases and there is no convincing evidence that the mode of delivery affects this. Hepatitis E (genotypes 1 and 2) is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with either worsening or improvement of autoimmune hepatitis, although improvement during pregnancy and rebound post-partum is the most common pattern seen. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones are more common during pregnancy and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made...
Box 24.60 Abnormal liver function tests in pregnancy

- Liver function tests: alkaline phosphatase (ALP) levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- Pre-existing liver disease: pregnancy is uncommon in cirrhosis because cirrhosis causes relative infertility. Varices can enlarge in pregnancy, and ascites should be treated with amiloride rather than spironolactone. Penicillin for Wilson’s disease and azathioprine for autoimmune liver disease should be continued during pregnancy. Autoimmune liver disease can flare up postpartum.
- Incidental: viral, autoimmune and drug-induced hepatitis must be excluded in the presence of an elevated aminotransferase (ALT). Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post partum, and are a cause of a raised ALT level. Biliary imaging with ultrasound and magnetic resonance cholangiopancreatography is safe. Endoscopic retrograde cholangiopancreatography to remove stones can be performed safely with shielding of the fetus from radiation.
- Pregnancy-related liver diseases: occur predominantly in the third trimester and resolve post partum. Maternal and fetal mortality and morbidity are reduced by expediting delivery.

Liver transplantation is an effective treatment for end-stage liver disease. However, the number of procedures is limited by cadaveric donor availability and 5%–15% of those listed for liver transplantation will die while awaiting a donor liver. The main complications of liver transplantation relate to long-term immunosuppression, rejection or disease recurrence in the liver graft.

Indications and contraindications

More than 30,000 liver transplants are performed worldwide each year. The main indications vary between regions. In Europe, the majority of liver transplants are for decompensated cirrhosis (56%), most frequently due to alcohol, hepatitis C or NAFLD, followed by hepatocellular carcinoma (17%), with 8% for acute liver failure. Fig. 24.42 shows indications for transplantation in the UK. In Asia, the most common indication is hepatocellular carcinoma related to hepatitis B. Patterns are changing over time, with reducing need for transplant in hepatitis C as a result of improved antiviral therapy, but increasing prevalence of NAFLD. Liver transplantation is increasingly being undertaken in older patients, with 30% of liver transplants in Europe now in patients aged over 60 years, but only a very small number aged over 70 years.

Transplant may be undertaken to improve survival in advanced liver disease or to alleviate symptoms. Common indications for elective transplant assessment are listed in Box 24.61. There are various criteria for HCC based on the size and number of lesions and level of serum alpha-fetoprotein (as these factors predict risk of recurrence post-transplant). Current UK guidelines allow transplant for a single lesion below 5 cm, or up to five lesions all below 3 cm, provided there is no macrovascular invasion or extrahepatic spread. Larger lesions may be suitable if stable following treatment. Specific criteria exist for patients with acute liver failure, depending on aetiology.

The main contraindications to transplantation are extrahepatic sepsis or malignancy, active alcohol or other substance misuse, and significant cardiorespiratory disease. Patients are matched for ABO blood group and size but do not require HLA matching with donors, as the liver is a relatively immune-privileged organ compared with the heart or kidneys.

Organ allocation is often based on greatest need, estimating short-term mortality using the MELD or UKELD scores (see Box 24.32). The United Kingdom has recently moved to a national allocation system based on Transplant Benefit Score, which uses donor and recipient variables to calculate the difference between the mortality without transplant (need) and the predicted 5-year survival with transplant (utility), to identify those with the greatest net benefit.

Approaches to increase the availability of donor organs include:

- Split liver transplantation. Due to the liver’s regenerative capacity, a cadaveric donor liver can be split into two, with the larger right lobe used in an adult and the smaller left lobe used in a child.
- Living donor transplantation. This is normally performed using the left lateral segment or the right lobe from a healthy donor. The donor mortality is significant, at 0.5%–1%. Pre-operative assessment includes looking at donor liver size and psychological status.
- Use of marginal grafts. Higher-risk livers (older donors, steatotic livers, non-heart-beating donors) are being used in selected patients. Novel organ perfusion technologies may help to improve graft selection and outcomes in this group.
- Increased donation. Improved infrastructure to support organ donation, increased public awareness of transplantation and changes to consent process (‘opt-out’, or presumed consent) may all increase donation rates.

**Complications**

<table>
<thead>
<tr>
<th>Early complications</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Primary graft non-function</strong></td>
</tr>
<tr>
<td>This is due to a severe ischaemia–reperfusion injury, resulting in irreversible graft failure and requiring early re-transplantation in around 4%–6% of recipients. Factors that increase the likelihood of primary non-function include increasing donor age, degree of steatosis in the liver and the length of ischaemia.</td>
</tr>
<tr>
<td><strong>Technical complications</strong></td>
</tr>
<tr>
<td>These include hepatic artery thrombosis, which may necessitate re-transplantation. Anastomotic biliary strictures can also occur; these may respond to endoscopic stenting, or require surgical reconstruction. Portal vein thrombosis following transplant is rare.</td>
</tr>
<tr>
<td><strong>Rejection</strong></td>
</tr>
<tr>
<td>Lifelong immunosuppression is required in most liver transplant recipients, although at lower levels than with kidney or heart/lung transplants. Immunosuppression is maximal in the early post-operative period, with reducing levels over time. A number of different regimens are used but the majority include a calcineurin inhibitor (usually tacrolimus) with or without an antimetabolite (azathioprine or mycophenolate) or tapersing steroids. Some patients can eventually be maintained on a single agent. Acute cellular rejection occurs in 15%–25% of patients, commonly presenting as raised liver enzymes at 5–30 days post-transplant, but can arise later. This normally responds to 3 days of high-dose intravenous methylprednisolone.</td>
</tr>
<tr>
<td><strong>Infections</strong></td>
</tr>
<tr>
<td>Bacterial infections, such as pneumonia and wound infections, can occur in the first few weeks after transplantation. Opportunistic infections are also seen, and prophylaxis against fungal infections and Pneumocystis jirovecii may be given during the first few months. Cytomegalovirus (primary infection or reactivation) is common in the 3 months after transplantation and can cause fevers, bone marrow suppression and hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk and are usually given prophylactic antiviral therapy, such as valganciclovir. Patients with latent tuberculosis should receive prophylaxis against reactivation.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Late complications</th>
</tr>
</thead>
<tbody>
<tr>
<td>Late complications are mostly consequences of long-term immunosuppression. These include malignancy (especially skin cancers and lymphoma), renal failure and cardiovascular disease. Weight gain is common following liver transplantation, leading to obesity and diabetes. Chronic rejection is rare, occurring in only 5% of cases. Recurrence of the initial disease can occur, especially with autoimmune liver diseases or hepatocellular carcinoma.</td>
</tr>
</tbody>
</table>

**Prognosis**

Current UK data show 1-year survival for patients transplanted for cirrhosis of 94%, with 5-year survival of 84%. Outcomes are worse in patients transplanted for acute liver failure as they often have multi-organ failure at the time of transplantation, and in patients transplanted for hepatocellular carcinoma, due to disease recurrence.

**Cholestatic and biliary disease**

The concepts of biliary and cholestatic disease, and the important distinctions between them, can be a source of confusion. ‘Cholestatic’ relates to impaired bile flow, usually detected as a biochemical abnormality (typically, elevation of ALP and elevation in serum bile acid levels and bilirubin). This can be due to failure of bile acid transport across the hepatocyte membrane, or physical obstruction of the bile duct. ‘Biliary disease’ relates to pathology at any level from the small intrahepatic bile ducts to the sphincter of Oddi. Although there is very significant overlap between cholestatic and biliary disease, there are scenarios where cholestasis can exist without biliary disease (transporter disease or pure drug-induced cholestasis) and where biliary disease can exist without cholestasis (when disease of the bile duct does not impact on bile flow).

**Chemical cholesta**

Pure cholestasis can occur as an inherited condition (p. 906), as a consequence of cholestatic drug reactions (p. 906) or as acute cholestasis of pregnancy. A more frequent, but less recognised, acquired biochemical cholestasis occurs in sepsis (‘cholangitis lenta’). This biochemical phenomenon is one of the causes of LFT abnormality in sepsis. Also termed subacute non-suppurative cholangitis, it is characterised by inspissated bile plugs in dilated bile ductules in the absence of mechanical obstruction. It does not require specific treatment and has a prognostic significance conferred by the underlying septic process. Mutations in the biliary transporter proteins on the hepatocyte canalicular membrane (familial intrahepatic cholestasis 1, FIC1), illustrated in Fig. 24.7, have been shown to cause an inherited intrahepatic biliary disease in childhood, characterised by raised ALP levels and progression to a biliary cirrhosis. It is also becoming increasingly clear that these proteins contribute to intrahepatic biliary disease in adulthood.

**Benign recurrent intrahepatic cholestasis**

Benign recurrent intrahepatic cholestasis (BRIC) is a rare autosomal recessive genetic disorder characterised by recurrent episodes of cholestatic jaundice lasting weeks to months. It usually presents in adolescence. Prodromal symptoms include pruritus, nausea, vomiting and weight loss. Patients are asymptomatic between episodes. Blood tests typically show conjugated hyperbilirubinaemia with elevated alkaline phosphatase. Cholangiography shows no evidence of biliary obstruction. Liver biopsy shows cholestasis during episodes but is normal between episodes.

BRIC is associated with mutations in the genes for two bile acid transporters: ATP8B1 (BRIC1) encoding FIC1 and ABCB11 (BRIC2) encoding the bile salt export pump (BSEP). Treatment is required to relieve symptoms and the long-term prognosis is good.
Intrahepatic biliary disease

**Inflammatory and immune disease**

The small intrahepatic bile ducts appear to be specifically vulnerable to immune injury, and ductopenic injury (‘vanishing bile duct syndrome’) can be a feature of a number of chronic conditions, including graft-versus-host disease (GVHD), sarcoidosis and, in the setting of liver transplantation, ductopenic rejection. Intrahepatic small bile duct injury occurs most frequently in primary biliary cholangitis, an autoimmune cholestatic disease, and less frequently in primary sclerosing cholangitis (see Box 24.54).

**Carolí’s disease**

Carolí’s disease and Carolí’s syndrome are rare congenital disorders characterised by multifocal saccular dilatation of the intrahepatic bile ducts. Bile duct ectasia may involve the entire liver, a lobe or a single segment. In Carolí’s disease, biliary ectasia occurs in isolation. However, in the more common variant, Carolí’s syndrome, the bile duct dilatation is associated with congenital hepatic fibrosis. The molecular pathogenesis is incompletely understood. Most cases are transmitted in an autosomal recessive manner and are associated with autosomal recessive polycystic kidney disease (ARPKD). In both conditions, focal dilatation of bile ducts leads to cholestasis with formation of biliary sludge and intraductal calculi. Recurrent attacks of cholangitis require antibiotic therapy and predispose to hepatic abscess formation. There is an increased risk of cholangiocarcinoma affecting 2.5%–16% of patients. Prognosis is generally poor. Localised disease may be treated by segmental liver resection. Patients with diffuse disease complicated by recurrent biliary sepsis or portal hypertension may require liver transplantation.

**Congenital hepatic fibrosis**

Congenital hepatic fibrosis (CHF) is a rare developmental disorder characterised by broad bands of fibrous tissue linking portal tracts and irregular-shaped proliferating bile ducts, resulting from ductal plate malformation. CHF may be inherited in an autosomal recessive manner and is associated with a range of disorders with multistystem involvement, including: Carolí’s syndrome, polycystic kidney disease, Joubert syndrome and Bardet–Biedl syndrome. The renal tubules may show cystic dilatation (medullary sponge kidney) and renal cysts/renal failure may develop. The condition typically present in childhood or early adulthood, although late presentation is described. Patients may present with symptoms of portal hypertension, including painful splenomegaly and variceal bleeding with preserved hepatic function, or with symptoms of cholestasis and recurrent cholangitis (Carolí’s syndrome). However, patients frequently present with symptoms related to other organ systems (e.g. kidney, central nervous system).

**Cystic fibrosis**

The term cystic fibrosis-associated liver disease (CFLD) encompasses the range of liver disease seen in patients with cystic fibrosis. Liver function test abnormalities are common, with persistent abnormalities affecting 40% of patients with cystic fibrosis. Biliary cirrhosis develops in 5%–10% of individuals by adolescence/early adulthood when complications such as varical haemorrhage may occur. Non-cirrhotic portal hypertension may develop as a consequence of pre-sinusoidal obliterative portal venopathy. UDCA improves liver biochemistry but it is unclear whether the drug can prevent progression of liver disease. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of biliary and pancreatic disease.

Extrahepatic biliary disease

Diseases of the extrahepatic biliary tree typically present with the clinical features of impared bile flow (jaundice, itch and fat malabsorption). Obstructive disease is frequently a consequence of ductal gallstones, sometimes with associated infection or inflammatory strictures, or post-surgical strictures. Malignant diseases (cholangiocarcinoma or carcinoma of the head of pancreas) should be considered in all patients with extrahepatic biliary obstruction. PSC frequently involves the extrahepatic biliary tree and its differential, IgG4 disease, is an important and potentially treatable cause of disease.

**Choledochal cysts**

Choledochal cysts are uncommon congenital cysts of the biliary tree (Fig. 24.43). They are usually diagnosed in the first decade of life. The majority cause diffuse dilatation of the common bile duct (type I). Others represent true diverticulae of the common bile duct (type II), dilatation of the intra-duodenal bile duct at the pancreatico-biliary junction (type III) or dilatation of the intrahepatic and/or the extrahepatic biliary ducts (type IV). Type V choledochal cysts are subdivided into those affecting the intrahepatic and extrahepatic ducts (type IVA) or multiple cysts affecting extrahepatic ducts with normal intrahepatic ducts (type IVB). Type V choledochal cysts refer to one or more cystic dilatations of intrahepatic ducts with normal extrahepatic ducts, with multiple cystic dilatations of intrahepatic ducts referred to as Carolí’s disease. Children may present with abdominal mass, jaundice or biliary peritonitis from cyst rupture. Adults more commonly present with jaundice, abdominal pain and cholangitis. Liver abscess and biliary cirrhosis may develop. There is an increased incidence of cholangiocarcinoma. Cyst excision with hepaticojenoanostomy is the treatment of choice.

**Secondary biliary cirrhosis**

Secondary biliary cirrhosis develops after prolonged large duct biliary obstruction due to gallstones, benign bile duct strictures or sclerosing cholangitis (see below). Carcinomas rarely cause secondary biliary cirrhosis because few patients survive long enough. The clinical features are those of chronic cholestasis with episodes of ascending cholangitis or even liver abscess. Cirrhosis, ascites and portal hypertension are late features. Relief of biliary obstruction may require endoscopic or surgical intervention. Cholangitis dictates treatment with antibiotics, which can be given continuously if attacks recur frequently.

**Gallstones**

Gallstone formation is the most common disorder of the biliary tree and it is unusual for the gallbladder to be diseased in the absence of gallstones. In high-income countries, gallstones occur in 7% of males and 15% of females aged 18–65 years, with an overall prevalence of 11%. In individuals under 40 years there is a 3:1 female preponderance, whereas in older people the sex ratio is about equal. Gallstones are less frequent in Asia and Africa. There has been much debate over the role of diet

---

### Fig. 24.43 Classification and frequency of choledochal cysts. Adapted from the Todani Classification of Choledochal Cysts (1977).
in cholesterol gallstone disease; an increase in dietary cholesterol, fat, total calories and refined carbohydrate or lack of dietary fibre has been implicated.

Pathophysiology

Gallstones are conventionally classified into cholesterol or pigment stones, although the majority are of mixed composition. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which are radio-opaque. Gallstone formation is multifactorial and the factors involved are related to the type of gallstone (Boxes 24.62 and 24.63).

Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease, the liver produces bile that contains an excess of cholesterol because there is either a relative deficiency of bile salts or a relative excess of cholesterol (‘lithogenic’ bile). Abnormalities of bile salt synthesis and circulation, cholesterol secretion and gallbladder function may make production of lithogenic bile more likely.

Pigment stones

Brown, crumbly pigment stones are almost always the consequence of bacterial or parasitic biliary infection. They are common in the Far East, where infection allows bacterial β-glucuronidase to hydrolyse conjugated bilirubin to its free form, which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in high-income countries is not satisfactorily explained. Haemolysis is important as a contributing factor for the development of black pigment stones that occur in chronic haemolytic disease.

Biliary sludge

This describes gelatinous bile that contains numerous microspheraliths of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

Clinical features

Only 10% of individuals with gallstones develop clinical evidence of gallstone disease. However, once symptoms occur they are likely to recur. Symptomatic stones within the gallbladder (Box 24.64) manifest as either biliary pain (‘biliary colic’) or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term ‘biliary colic’ is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic.

Typically, the pain occurs suddenly and persists for several hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20%) and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrahepatic disease, oesophagitis, myocardial infarction or aortic dissection.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as ‘gallstone dyspepsia’. These symptoms are not now recognised as being caused by gallstones and are best regarded as functional dyspepsia. Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing ‘limy’ bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of ‘porcelain’ gallbladder results.

Gallstones in the gallbladder (cholecystolithiasis) migrate to the common bile duct (choledocholithiasis; p. 916) in approximately 10%–20% of patients and can cause biliary colic. Rarely, stones can fistulate between the gallbladder and the gastric outlet or duodenum (causing obstruction, known as Bouvieret syndrome) or colon. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may then impact either at the terminal ileum or sigmoid colon. The resultant intestinal obstruction may be followed by ‘gallstone ileus’. Gallstones impacted in the cystic duct may cause obstruction to the common hepatic duct and the clinical picture of extrahepatic biliary diseases (‘Mirizzi syndrome’, with its important differential of malignant bile duct structure). The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due to oedema at the ampulla as the stone passes.
24.65 Gallbladder disease in old age

- **Gallstones:** by the age of 70 years, prevalence is around 30% in women and 19% in men.
- **Acute cholecystitis:** tends to be severe, may have few localising signs and is associated with a high frequency of empyema and perforation. If such complications supervene, mortality may reach 20%.
- **Cholecystectomy:** mortality after urgent cholecystectomy for acute uncomplicated cholecystitis is not significantly higher than in younger patients.
- **Endoscopic sphincterotomy and removal of common duct stones:** well tolerated by older patients, with lower mortality than surgical common bile duct exploration.
- **Cancer of the gallbladder:** a disease of old age, with a 1-year survival of 10%.

Fig. 24.44 Magnetic resonance cholangiopancreatogram showing multiple small stones in the gallbladder (large arrow), two larger stones in the distal common bile duct (smaller arrows) and also a cystic lesion in the head of pancreas (C).

passes into the duodenum. No stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage. Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease. It presents with biliary pain (often following cholecystectomy) with cholestatic LFTs and biliary dilatation, or acute pancreatitis, and is treated by ERCP and sphincterotomy.

Cancer of the gallbladder is increasing in frequency but in over 85% of cases is associated with the presence of gallstones. Previously, the diagnosis was typically made as an incidental histological finding following cholecystectomy for gallstone disease. Increasing awareness of the risk of gallbladder carcinoma and of the role played by polyps in the natural history has led to an increase in screening activity and prospective diagnosis. Biliary disease is common in the elderly and can be challenging to manage in frail patients (Box 24.65).

### Investigations

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has more than 84% sensitivity and 99% specificity for gallbladder stones (see Fig. 24.8). CT, MRCP (Fig. 24.44) and, increasingly, EUS are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema) but are inferior to ultrasound in defining their presence in the gallbladder. When recurrent attacks of otherwise unexplained acute pancreatitis occur, they may result from ‘microolithiasis’ in the gallbladder or common bile duct and are best assessed by EUS.

### Management

Asymptomatic gallstones found incidentally in the gallbladder should not be treated because the majority will never cause symptoms. Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy; the severity of symptoms should be balanced against the individual patient surgical risk in order to decide whether surgery is warranted. Asymptomatic common bile duct stones should also be removed due to the high risk of complications (Box 24.66).

#### Cholecystitis

### Acute cholecystitis

#### Pathophysiology

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a biliary tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage, which releases phospholipase, converting biliary lecithin to lyssolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in older patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

#### Clinical features

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic and acute cholecystitis may be difficult; features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness with guarding, worse on inspiration (Murphy’s sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual and suggest cholangitis. Jaundice occurs in less than 10% of patients and is usually due to passage of stones into the common bile duct, or to compression or even stricturing of the common bile duct following stone impaction in the cystic duct (Mirizzi syndrome). Gallbladder perforation occurs in 10%–15% of cases and gallbladder empyema may arise.

#### Investigations

Peripheral blood leucocytosis is common, except in older patients, in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis, which may be a potentially serious complication of gallstones. Only when the amylase is higher than 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur with many other causes of abdominal pain. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intrabiliary gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis but gallbladder empyema or perforation is best assessed by CT.

#### Treatment of gallstones

**Gallbladder stones**

- Cholecystectomy: laparoscopic or open
- Oral bile acids: chenodeoxycholic or ursodeoxycholic (low rate of stone dissolution)

**Bile duct stones**

- Endoscopic sphincterotomy and stone extraction
- Surgical bile duct exploration
- Lithotripsy (endoscopic or extracorporeal shock wave, ESWL)
Management
Medical
Medical management consists of bed rest, pain relief, antibiotics and intravenous fluids. Moderate pain can be treated with NSAIDs but more severe pain should be managed with opiates. A cephalosporin (such as cefuroxime) or piperacillin/tazobactam is the usual antibiotic of choice, but metronidazole is normally added in severely ill patients and local prescribing practice may vary. Cholecystitis usually resolves with medical treatment but the inflammation may progress to an empyema or perforation and peritonitis.

Surgical
Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. The operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. When cholecystectomy may be difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

Chronic cholecystitis
Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often at night and following a heavy meal. The clinical features are similar to those of acute calculus cholecystitis but milder. Patients may recover spontaneously or following analgesia and antibiotics. They are usually advised to undergo elective laparoscopic cholecystectomy.

Acute cholangitis
Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems, such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, fever (with or without rigors) and right upper quadrant pain are the main presenting features (‘Charcot’s triad’). Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.

Choledocholithiasis
Stones in the common bile duct (choledocholithiasis) occur in 10%–15% of patients with gallstones (Fig. 24.46), which have usually migrated from the gallbladder. Primary bile duct stones are rare but can develop within the common bile duct many years after a cholecystectomy, and are sometimes related to biliary sludge arising from dysfunction of the sphincter of Oddi. In Far Eastern countries, primary common bile duct stones are thought to follow bacterial infection secondary to parasitic infections with Clonorchis sinensis, Ascaris lumbricoides or Fasciola hepatica. Common bile duct stones can cause bile duct obstruction and may be complicated by cholangitis due to secondary bacterial infection, sepsis, liver abscess and biliary stricture.

Clinical features
Choledocholithiasis may be asymptomatic, may be found incidentally by operative cholangiography at cholecystectomy or on abdominal imaging, or may manifest as biliary colic, jaundice, cholangitis or pancreatitis. If the gallbladder is still present, it is usually small, fibrotic and impalpable.

Investigations
The LFTs show a cholestatic pattern. If cholangitis is present, the patient usually has a leucocytosis. Initial imaging is with transabdominal ultrasound which often show dilated extrahepatic and intrahepatic bile ducts, together with gallbladder stones (Fig. 24.46), but does not always reveal the cause of the obstruction in the common bile duct; 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. MRCP and EUS both have a high sensitivity for ductal stones, and can also help to define biliary anatomy prior to intervention. MRCP is often preferred as it is non-invasive.

Management
Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics, such as cefuroxime and metronidazole (local prescribing practice may vary). Blood cultures should be taken before the antibiotics are administered. Patients also require urgent decompression of the biliary tree and stone removal. ERCP with biliary sphincterotomy and stone extraction is the treatment of choice and is successful in about 90% of patients. In some complex cases cholangioscopy (‘SpyGlass’™) with electrohydraulic lithotripsy may be required. If ERCP fails, other approaches include percutaneous transhepatic drainage and combined (‘rendezvous’) endoscopic procedures, extracorporeal shock wave lithotripsy (ESWL) and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP. The CBD may be explored laparoscopically, either trans-cystic (via the gallbladder) or trans-ductal, or at laparotomy.

Fig. 24.45 Endoscopic retrograde cholangiopancreatogram showing common duct stones (arrows).

Fig. 24.46 Endoscopic ultrasonography (EUS) image showing a prominent common bile duct (CBD) containing a small stone (arrow) causing acoustic shadowing.
Recurrent pyogenic cholangitis

This disease occurs predominantly in South-east Asia. Biliary sludge, calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage and requires drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.

Tumours of the gallbladder and bile duct

Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually in those over the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70%–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder (‘porcelain gallbladder’) are at high risk of malignant change, and gallbladder polyps greater than 1 cm in size are associated with increased risk of malignancy; preventative cholecystectomy should be considered in such patients. Chronic infection with Salmonella, especially in areas where typhoid is endemic, is also a risk factor.

Carcinoma of the gallbladder may be diagnosed incidentally and is found in 0.2%–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and, later, persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and calcification of the gallbladder wall (‘porcelain gallbladder’) may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is prominent at diagnosis. Only a minority of pre-operatively diagnosed gallbladder cancers are suitable for resection. Palliative management is usually all that can be offered. Survival is generally short, death typically occurring within 1 year in patients presenting with symptoms.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is an uncommon tumour that can arise anywhere in the biliary tree, from the intrahepatic bile ducts (20%–25% of cases) and the confluence of the right and left hepatic ducts at the liver hilum (50%–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the incidence is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli’s disease and choledochal cysts (see Fig. 24.43). In the Far East, particularly northern Thailand, chronic liver fluke infection (Clonorchis sinensis) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of 5%–20%, although only 5% of CCA relate to primary sclerosing cholangitis.

Cirrhosis is a risk factor for intrahepatic cholangiocarcinoma. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths. The presentation is usually with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made using a combination of CT and MRI (see Fig. 24.10) but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19-9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. The sensitivity of biliary brushing cytology is low (20%–43%) but can be improved with analysis for chromosomal aneuploidy using fluorescent in situ hybridization (FISH). Endoscopic ultrasound–fine needle aspiration (EUS–FNA) of bile duct masses or lymph nodes is sometimes possible, and in specialist centres cholangioscopy with biopsy is now established. CCA can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20%–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. Liver transplant is generally not recommended as a treatment for CCA due to high recurrence rate and poor long-term survival. Neoadjuvant chemotherapy followed by liver transplant is effective in highly selected patients with perihilar CCA, but is not a widely accepted or available treatment.

Most patients with CCA are treated with stent insertion across the malignant biliary stricture, using endoscopic or percutaneous transhepatic techniques to achieve relief of jaundice (Fig. 24.47). Patients with unresectable disease may receive chemotherapy and selected

Fig. 24.47 Cholangiocarcinoma. A Endoscopic retrograde cholangiopancreatogram showing a malignant distal biliary stricture (arrow) and dilated duct above this. B A self-expanding metallic stent (SEMS) has been placed across the stricture to relieve jaundice (arrow).
patients may benefit from combined chemotherapy and radiotherapy. Loco-regional therapies with chemotherapy may be effective for locally advanced unresectable tumours, but particularly intrahepatic CCA. Palliation with endoscopic photodynamic therapy has provided encouraging results for extrahepatic CCA.

### Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relation to the ampulla of Vater and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour but staging by CT/MRI and EUS is essential. Ampullary carcinoma must be differentiated from carcinoma of the head of the pancreas and a CCA because these last two conditions both have a worse prognosis. Imaging may show a ‘double duct sign’ with dilatation of both the common bile duct and pancreatic duct due to obstruction at the ampulla. EUS is the most sensitive method of assessing and staging ampullary or periampullary tumours.

Curative surgical treatment can be undertaken by pancreaticoduodenectomy and the 5-year survival may be as high as 50%. If resection is impossible, palliative surgical bypass or stenting may be necessary.

### Benign gallbladder tumours

These are uncommon, often asymptomatic and usually found incidentally at operation or postmortem. Cholesterol polyps, sometimes associated with cholecystitis, papillomas and adenomas, are the main types.

### Miscellaneous biliary disorders

#### Functional gallbladder disorder

Functional gallbladder disorder refers to symptoms of biliary-type pain in the absence of gallstones, sludge or microthiasis. Gallstone disease needs to be excluded by means of abdominal US ± EUS to exclude microthiasis. Other diagnostic tests may be required to exclude peptic ulcer disease, pancreatitis or musculoskeletal syndromes. Cholecystokinin-stimulated hepatobiliary scintigraphy can be used to evaluate gallbladder ejection fraction.

Symptoms suggestive of functional gallbladder disorder often improve spontaneously so urgent surgical intervention is not required. Management involves patient education and reassurance. Pharmacological therapy with analgesia, neuromodulators and antispasmodics may be beneficial. Cholecystectomy can improve symptoms in many patients with recurrent functional biliary pain. It is suggested that a low gallbladder ejection fraction (<40%) may identify a subset of patients likely to benefit from surgery but evidence is contradictory.

### Post-cholecystectomy syndrome

Post-cholecystectomy syndrome refers to a complex of heterogeneous symptoms including abdominal pain and dyspepsia that recur and/or persist following cholecystectomy. It occurs in 10%–30% of patients depending on how the condition is defined, how actively symptoms are sought and what the original indication for cholecystectomy was. The syndrome occurs most frequently in women, in patients who have had symptoms for more than 5 years before cholecystectomy, and in cases where the operation was undertaken for non-calcific gallbladder disease. An increase in bowel frequency resulting from bile acid diarrhea occurs in about 5%–10% of patients after cholecystectomy and often responds to colestyramine (4–8 g daily). Severe post-cholecystectomy syndrome occurs in only 2%–5% of patients. The main causes are listed in Box 24.67.

The usual symptoms include right upper quadrant pain, flatulence, fatty food intolerance and occasionally jaundice and cholangitis. The LFTs may be abnormal and sometimes show cholestasis. Ultrasonography is used to detect biliary obstruction, and EUS or MRCP to seek common bile duct stones. If retained bile duct stones are excluded, sphincter of Oddi dysfunction should be considered (see below). Other investigations that may be required include upper gastrointestinal endoscopy, small bowel radiology and pancreatic function tests. The possibility of a functional illness should also be considered.

### Functional biliary sphincter disorders (‘sphincter of Oddi dysfunction’)

The sphincter of Oddi is a small smooth-muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. It has been believed that sphincter of Oddi dysfunction (SOD) was characterised by an increase in contractility that produces a benign non-calcific obstruction to the flow of bile or pancreatic juice. This may cause pancreaticobiliary pain, deranged LFTs or recurrent pancreatitis. Classification systems, based on clinical history, laboratory results, findings on investigation and response to interventions, are difficult because of the fluctuating nature of symptoms and the well-recognised placebo effect of interventions. SOD was previously classified into types I–III but these have been replaced by newer terminology (Boxes 24.68 and 24.69).

#### Clinical features

Patients with functional biliary sphincter disorders, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease:

- Patients with biliary sphincter disorders experience recurrent, episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.
- Patients with pancreatic sphincter disorders usually present with unexplained recurrent attacks of pancreatitis.

#### Investigations

The diagnosis is established by excluding gallstones, including microthiasis, and by demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry. This is not widely available, however, and is associated with a high rate of procedure-related pancreatitis. Hepatobiliary scintigraphy may have value in the second-line investigation of post-cholecystectomy syndrome.

#### Management

All patients with organic stenosis are treated with endoscopic sphincterotomy. The results are good but patients should be warned that there is a high risk of complications, particularly acute pancreatitis (10%–15%). Manometry should ideally be performed in all suspected functional sphincter of Oddi disorder patients, and results of sphincterotomy in those with high pressures are good, but this should be avoided in
patients with functional biliary-type pain as it is of no benefit. Medical therapy with nifedipine and/or low-dose amitriptyline may be tried. Pancreatic SOD can be treated with biliary sphincterotomy, carried out in specialist centres, but this should be undertaken with caution and careful consideration.

Routine prophylactic pancreatic duct stenting in patients undergoing ERCP for sphincter of Oddi disorders is no longer encouraged. Prophylactic administration of rectal NSAIDs (e.g. diclofenac 100mg) is recommended instead because this significantly reduces the risk of procedure-related acute pancreatitis.

### Cholesterolosis of the gallbladder

In this condition, lipid deposits in the submucosa and epithelium appear as multiple yellow spots on the pink mucosa, giving rise to the description ‘strawberry gallbladder’. Cholesterolosis of the gallbladder is usually asymptomatic. Larger polypoid deposits occur in a third of cases leading to the formation of cholesterol polyps that can detach resulting in complications similar to small gallstones, including right upper quadrant pain. Small, fixed filling defects may be visible on ultrasonography; the radiologist can usually differentiate between gallstones and cholesterolosis. The condition is usually diagnosed at cholecystectomy; if the diagnosis is made radiologically, cholecystectomy may be indicated, depending on symptoms.

### Adenomyomatosis of the gallbladder

In this condition, there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitansky–Aschoff sinuses. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It may be diagnosed by oral cholecystography, when a halo or ring of opacified diverticula can be seen around the gallbladder. Other appearances include deformity of the body of the gallbladder or marked irregularity of the outline. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a ‘Phrygian cap’. Most patients are treated by cholecystectomy but only after other diseases in the upper gastrointestinal tract have been excluded.

### IgG4-associated cholangitis

This often presents with obstructive jaundice and is described on page 901.

This page intentionally left blank
24.1 A 52-year-old homeless man with a history of alcohol dependency is admitted to hospital with a 2-month history of weight loss, fever, cough and abdominal distension. Liver ultrasound scan shows moderate ascites with normal liver appearance with patent portal/hepatic veins and no focal lesions. A diagnostic ascitic tap is performed:

- Microscopy: WCC 350 cell/mm³, polymorphs 100 cells/mm³, lymphocytes 250 cells/mm³. No organisms seen.
- Ascitic protein: 28 g/L
- Ascitic albumin: 19 g/L
- Serum albumin: 26 g/L
- Cytology: inflammatory cells only.

What is the most likely cause of this patient’s ascites?

A. Spontaneous bacterial peritonitis
B. Tuberculosis
C. Budd–Chiari syndrome
D. Pancreatic cancer
E. Alcohol-related liver disease with cirrhosis

Answer: B.

Tuberculosis is a cause of high-protein ascites with a low serum–ascites albumin gradient (SAAG) (< 11 g/L). Elevated lymphocytes are typically seen on ascites microscopy. Acid-fast bacilli (AFB) may be seen but prolonged TB culture may be required for definitive diagnosis. Budd–Chiari syndrome is a cause of ascites with high SAAG (> 11 g/L). Disseminated malignancy with peritoneal involvement is a cause of exudative ascites with low SAAG (< 11 g/L) but normal CT imaging and ascites cytology makes this diagnosis less likely. Ascites due to liver cirrhosis has a high SAAG (> 11 g/L). Spontaneous bacterial peritonitis is diagnosed by the finding of elevated polymorphs (> 250 cells/mm³) in ascitic fluid.

24.2 A 56-year-old woman with autoimmune hepatitis and cirrhosis is admitted with agitation and confusion. Examination reveals a flapping tremor and a diagnosis of hepatic encephalopathy is made. Which of the following would be suitable first-line therapy?

A. Dietary protein restriction
B. Oral lactulose
C. Rifaximin
D. L-ornithine L-aspartate (LOLA)
E. Benzodiazepines

Answer: B.

Hepatic encephalopathy is caused by disturbed brain function provoked by gut-derived neurotoxins that are normally metabolised by the liver and excluded from the systemic circulation. Treatment aims to reduce toxin production in the bowel. First-line therapy is with lactulose (15–30 mL three times daily) to promote regular bowel motions. Rifaximin is a non-absorbable antibiotic that reduces bacterial load in the gut and is helpful in treating recurrent episodes of encephalopathy. L-ornithine L-aspartate (LOLA) is an amino acid supplement that may be useful in reducing ammonia levels and improving encephalopathy in patients with refractory disease. Dietary protein restriction is no longer recommended in the treatment of encephalopathy and may worsen nutritional state. Sedative drugs including opiates and benzodiazepines may precipitate/worsen encephalopathy in cirrhotic patients and should be avoided in these patients.

24.3 An 18-year-old man presents to his family doctors having noticed mild jaundice having been treated with a course of oral amoxicillin for lower respiratory tract infection. Abdominal ultrasound is normal. His liver biochemistry reveals:

- Bilirubin 60 μmol/L
- Direct bilirubin 9 μmol/L
- ALT 23 U/L
- ALP 82 U/L
- GGT 35 U/L
- Albumin 40 g/L

What is the most likely diagnosis?

A. Drug-induced liver injury
B. Primary sclerosing cholangitis
C. Gilbert syndrome
D. Dubin–Johnston syndrome
E. Hepatitis E infection

Answer: C.

Gilbert syndrome is an inherited disorder of bilirubin metabolism characterised by isolated elevation of bilirubin, usually in the context of physical stress or illness. It presents with isolated elevation of unconjugated bilirubin (indirect bilirubin) and otherwise normal liver enzymes. Drug-induced liver injury may present with jaundice but there would be additional liver enzyme disturbance following either a hepatic, cholestatic or mixed pattern. Dubin–Johnston syndrome is an inherited disorder of bilirubin metabolism associated with conjugated (direct) hyperbilirubinaemia. Hepatitis E infection may present with jaundice in associated with an acute hepatitis with elevated transaminase levels (ALT/AST).

24.4 A 42-year-old man presents with abnormal liver enzymes, on a background of early onset emphysema. His serum α₁-AT level is 0.03 g/L (normal range 1.1–2.1 g/L). Which of the following statements about α₁-antitrypsin deficiency is true?

A. Most liver disease is due to the PiMZ genotype
B. Lung disease occurs due to the accumulation of abnormally folded protein in alveolar cells
C. Inheritance is autosomal dominant
D. It can present as neonatal jaundice
E. A liver biopsy is required for diagnosis

Answer: D.

Alpha-1-antitrypsin deficiency can present in a range of ways, from neonatal cholestatic jaundice through to adult-onset cirrhosis. Inheritance is autosomal recessive. The normal genotype is PiMM and most disease is due to PiZZ. Liver disease occurs due to accumulation of abnormally folded protein in hepatocytes, whereas lung disease is a result of unopposed neutrophil elastase activity. Diagnosis is usually based on serum α₁-AT levels and genotyping.
A 56-year-old man with alcohol-related cirrhosis is admitted with ascites and hepatic encephalopathy, and is noted to have loss of muscle mass. The Na is 131 mmol/L (normal range 135–145). Which of the following would you advise the patient?

A. Salt intake should be increased in view of hyponatraemia
B. Fluid intake should be restricted
C. Protein intake should be restricted in view of encephalopathy
D. Calorie intake should be 15–20kCal/kg per day
E. A bedtime snack is recommended

Answer: E.

Malnutrition is common in cirrhosis. A bedtime snack will avoid prolonged fasting which can trigger catabolism. Calorie intake should be at least 35kCal/kg per day, with a protein intake of 1.2–1.5g/kg. A no-added-salt diet is recommended in ascites, and fluid restriction is rarely needed (and may exacerbate renal impairment in this case).

Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems, but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities must include a general history and examination, as well as a search for symptoms and signs of specific primary haematologica and other disorders that result in abnormalities of red cells, white cells, platelets, coagulation, lymph nodes and lymphoreticular tissues.

**Lymphadenopathy**

Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.

**Anaemia**

Symptoms and signs help to indicate the clinical severity of anaemia. A full history and examination is needed to identify the underlying cause.

**Bleeding**

Bleeding can be due to congenital or acquired abnormalities in the coagulation system. History and examination help to clarify the severity and the underlying cause of the bleeding problem.

**Examination of the spleen**

- Move your hand up from the right iliac fossa, towards the left upper quadrant on expiration.
- Keep your hand still and ask the patient to take a deep breath through the mouth to feel the spleen edge being displaced downwards.
- Place your left hand around the patient’s lower ribs and approach the costal margin to pull the spleen forwards.
- To help palpate a spleen that is only slightly enlarged, roll the patient on to the right side and examine as before.

**Characteristics of the spleen**

- Notch
- Superficial
- Dull to percussion
- Cannot get examining hand between ribs and spleen
- Moves well with respiration

**i Lymphadenopathy**

**History**

- Speed of onset, rate of enlargement
- Painful or painless
- Associated symptoms: weight loss, night sweats, itch

**Examination**

- Sites: localised, generalised
- Size (cm)
- Character: hard, soft, rubbery
- Fixed, mobile
- Search area that node drains for abnormalities (e.g. dental abscess)
- Other general examination (e.g. joints, rashes, finger clubbing)
Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting humans (anaemias) to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur as a consequence of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

**Functional anatomy and physiology**

Blood flows throughout the body in the vascular system, and consists of:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which defend against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding
- plasma, which contains proteins with many functions, including antibodies and coagulation factors.

**Haematopoiesis**

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the yolk sac, liver and spleen, and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow) so that, in adults, normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red marrow can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made up of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 25.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and also phagocytoses nuclei from red cells prior to their release into the circulation. Megakaryocytes are large cells that produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells that normally represent less than 5% of the marrow population and are scattered throughout the intertrabecular spaces.

**Stem cells**

All blood cells are derived from pluripotent haematopoietic stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e., make more stem cells) or differentiate to produce a hierarchy of lineage-committed progenitor cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU–GM (colony-forming unit – granulocyte, monocyte) is a progenitor cell that produces granulocytic and monocytic lines, CFU–E produce erythroid cells, and CFU–Meg produce megakaryocytes and ultimately platelets (Fig. 25.2).

Growth factors, produced in bone marrow stromal cells and elsewhere, control the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as interleukin-3 (IL-3), stem cell factor (SCF) and granulocyte, macrophage–colony-stimulating factor (GM–CSF), act on a wide number of cell types at various stages of differentiation. Others, such as erythropoietin, granulocyte–colony-stimulating factor (G–CSF) and thrombopoietin (Tpo), are lineage-specific. Many of these growth factors are now synthesised by recombinant DNA technology and used as treatments: for example, erythropoietin to correct renal anaemia and G–CSF to hasten neutrophil recovery after chemotherapy.

The bone marrow also contains stem cells that can differentiate into non-haematological cells. Mesenchymal stem cells differentiate into skeletal muscle, cartilage, cardiac muscle and fat cells while others differentiate into nerves, liver and blood vessel endothelium. This is termed stem cell plasticity and may have exciting clinical applications in the future (Ch. 3).

**Blood cells and their functions**

**Red cells**

Red cell precursors formed in the bone marrow from the erythroid (CFU–E) progenitor cells are called erythroblasts or normoblasts (Fig. 25.3). These divide and acquire haemoglobin, which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte, which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge ("polychromasia").

![Fig. 25.1 Structural organisation of normal bone marrow.](image-url)
Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by erythropoietin, a polypeptide hormone produced by renal interstitial peritubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure causes anaemia, which can be treated with exogenous recombinant erythropoietin or similar pharmacological agents called erythropoiesis-stimulating agents, e.g. darbepoetin.

Normal mature red cells circulate for about 120 days. They are 8 μm biconcave discs lacking a nucleus, but filled with haemoglobin, which delivers oxygen to the tissues. In order to pass through the smallest capillaries, the red cell membrane is deformable, with a lipid bilayer to which a ‘skeleton’ of filamentous proteins is attached via special linkage...
proteins (Fig. 25.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 25.8D). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 25.4). The ABO and Rhesus systems are the most commonly recognised, but over 400 blood group antigens have been described.

**Haemoglobin**

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment termned haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A (αα/ββ) represents over 90% of adult haemoglobin, whereas haemoglobin F (αγ/γγ) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe²⁺), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains ‘swing’ closer together; they move apart as oxygen is lost. In the ‘open’ deoxygenated state, 2,3-bisphosphoglycerate (2,3-BPG), a product of red cell metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 25.5). The position of this curve depends on the concentrations of 2,3-BPG, H⁺ ions and CO₂; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g. when red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3-BPG and has a left-shifted oxygen dissociation curve, which, together with the low pH of fetal blood, ensures fetal oxygenation. Strong oxidising agents, such as dapsone, can convert the ferrous iron in haemoglobin to its ferric state (Fe³⁺). The resultant methaemoglobin also has a left-shifted oxygen dissociation curve, which can result in tissue hypoxia (see Fig. 10.1).

Genetic mutations affecting the haem-binding pockets of globin chains or the ‘hinge’ interactions between globin chains result in haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16, and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains results in the thalassaemias (p. 962). Defects in haem synthesis cause the porphyrias (Ch. 19).

**Destruction**

Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for reuse in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney.
as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

White cells

White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 25.12). Granulocytes and monocytes are formed from bone marrow CFU–GM progenitor cells during myelopoiesis. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleoli. As the cells divide and mature, the nucleus segments and the cytoplasm acquires specific neutrophilic, eosinophilic or basophilic granules (see Fig. 25.3). This takes about 14 days. The cytokines G–CSF, GM–CSF and M–CSF are involved in the production of myeloid cells, and recombinant G–CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally found only in the marrow, but may appear in the circulation in response to infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a ‘leucocythembroid’ picture; this indicates a serious disturbance of marrow function.

Neutrophils

Neutrophils, the most common white blood cells in the blood of adults, are 10–14 μm in diameter, with a multinucleated nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (see Ch. 4). A large storage pool of mature neutrophils exists in the bone marrow. Every day, some 10¹¹ neutrophils enter the circulation, where cells may be circulating freely or attached to endothelium in the marginalising pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in the circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

Eosinophils

Eosinophils represent 1%–6% of the circulating white cells. They have a similar size to neutrophils, but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (Ch. 13). They are also involved in allergic reactions (e.g. atopic asthma, Ch. 17; see also Ch. 4).

Basophils

These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules that obscure the nucleus. Mast cells resemble basophils, but are found only in the tissues. These cells are involved in hypersensitivity reactions (Ch. 4).

Monocytes

Monocytes are the largest of the white cells, with a diameter of 12–20 μm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into tissue, where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1).

Lymphocytes

Lymphocytes are derived from pluripotent haematopoietic stem cells in the bone marrow. There are two main types: T cells (which mediate cellular immunity) and B cells (which mediate humoral immunity) (Ch. 4). Lymphoid cells that migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow.

The majority (about 80%) of lymphocytes in the circulation are T cells. Lymphocytes are heterogeneous, the smallest being the size of red cells and the largest the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm but the larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations have specific functions and lifespan can vary from a few days to many years. Cell surface antigens (‘cluster of differentiation’ (CD) antigens), which appear at different points of lymphocyte maturation and indicate the lineage and maturity of the cell, are used to classify lymphomas and lymphoid leukaemias.

Haemostasis

Blood must be maintained in a fluid state in order to function as a transport system, but must be able to solidify to form a clot following vascular injury in order to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets, von Willebrand factor, coagulation factors, natural anticoagulants and fibrinolytic enzymes (Fig. 25.6 and see Fig. 25.18). Dysfunction of any of these components may result in haemorrhage or thrombosis.

Platelets

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic progenitor cells (CFU–Meg) divide to form megakaryoblasts, which undergo a process called ‘endomitotic reduplication’, in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Large numbers of platelets then fragment off from each megakaryocyte into the circulation. The formation and maturation of megakaryocytes is stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the reticuloendothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.

Under normal conditions, platelets are discoid, with a diameter of 2–4 μm (Fig. 25.7). The surface membrane invaginates to form a tubular network, the canalscular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs that inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopido- grel, prasugrel and ticagrelor (adenosine diphosphate (ADP)-mediated activation inhibitors), dipyridamole (phosphodiesterase inhibitor), and abciximab, tirofiban and eptifibatide (which prevent fibrinogen binding to glycoprotein IIb/IIIa (Vw beta3 integrin); see Fig. 25.19).

Clotting factors

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman numerals. When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix ‘a’. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways: it is initiated by the extrinsic (or tissue factor) pathway and amplified by the ‘intrinsic’ pathway (see Fig. 25.6D).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow their participation in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is inhibited by warfarin, and this is the basis of the anti-coagulant effect of coumarins (p. 947). Inherited (e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.
HAEMATOLOGY AND TRANSFUSION MEDICINE

Fig. 25.6 The stages of normal haemostasis. 

**A** Stage 1. Pre-injury conditions encourage flow. The vascular endothelium produces substances (including nitric oxide, prostacyclin and heparans) to prevent adhesion of platelets and white cells to the vessel wall. Platelets and coagulation factors circulate in a non-activated state. **B** Stage 2. Early haemostatic response: platelets adhere; coagulation is activated. At the site of injury, the endothelium is breached, exposing subendothelial collagen. Small amounts of tissue factor (TF) are released. Platelets bind to collagen via a specific receptor, glycoprotein Ia (GPIa), causing a change in platelet shape and its adhesion to the area of damage by the binding of other receptors (GPIb and GPIb/IIIa) to von Willebrand factor and fibrinogen, respectively. Coagulation is activated by the tissue factor (extrinsic) pathway, generating small amounts of thrombin. **C and D** Stage 3. Fibrin clot formation: platelets become activated and aggregate; fibrin formation is supported by the platelet membrane; stable fibrin clot forms. The adherent platelets are activated by many pathways, including binding of adenosine diphosphate (ADP), collagen, thrombin and adrenaline (epinephrine) to surface receptors. The cyclooxygenase pathway converts arachidonic acid from the platelet membrane into thromboxane A$_2$, which causes aggregation of platelets. Activation of the platelets results in release of the platelet granule contents, enhancing coagulation further (see Fig. 25.7). Thrombin plays a key role in the control of coagulation: the small amount generated via the TF pathway massively amplifies its own production; the ‘intrinsic’ pathway becomes activated and large amounts of thrombin are generated. Thrombin directly causes clot formation by cleaving fibrinopeptides (FPs) from fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see E and F). 

**E** Stage 4. Limiting clot formation: natural anticoagulants reverse activation of coagulation factors. Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as X, IX and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates Xla and Xa. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor, protein S (PS), and cleaves Va and Vila. PC and PS are vitamin K-dependent and are depleted by coumarin anticoagulants such as warfarin. 

**F** Stage 5. Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair. The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (t-PA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products, including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by α₂-antiplasmin and α₁-macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.
Fig. 25.6, cont’d

Fig. 25.7 Normal platelet structure. The platelet surface is populated by glycoproteins, which bind to key structures including fibrinogen, collagen and von Willebrand factor and cell surface receptors for thrombin, ADP and adrenaline (epinephrine). Through internal signalling pathways, platelet activation causes degranulation of alpha and dense granules, which ultimately results in platelet aggregation. Blockade of these pathways by drugs such as aspirin, clopidogrel, ticagrelor, tirofiban and abciximab forms the basis of antiplatelet therapy. (ADP = adenosine diphosphate; GP = glycoprotein)
Investigation of diseases of the blood

The full blood count

To obtain a full blood count (FBC), anticoagulated blood is processed through automated blood analysers that use a variety of technologies (particle-sizing, radiofrequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices that give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a number of conditions can lead to spurious results (Box 25.1). The reference ranges for a number of common haematological parameters in adults are given in Chapter 35 and the effects of age are shown in Box 25.6.

Blood film examination

Although technical advances in full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the ‘blood film’) can often yield valuable information (Box 25.2 and Fig. 25.5). Analysers cannot identify abnormalities of red cell shape and content (e.g. Howell–Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

Bone marrow examination

In adults, bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow can be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 25.9). A bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome (karyotyping) and molecular studies, including next generation sequencing (NGS) to identify mutated genes as part of the assessment of malignant diseases and bone marrow failure syndromes. Marrow can be cultured for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow fibrosis, and infiltration by abnormal cells such as metastatic carcinoma.

Investigation of coagulation

Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 923), there are recommended screening tests (Box 25.3). Physiological activation of coagulation is predominantly by tissue factor, with amplification of the process by the small amounts of thrombin formed as a result. For ease of description, the terms extrinsic, intrinsic and common pathways are still used (see Fig. 25.6D).

Coagulation tests measure the time to clot formation in vitro in a platelet poor plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The tissue factor (‘extrinsic’) pathway (see Fig. 25.6D) is assessed by the prothrombin time (PT), and the ‘intrinsic’ pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin (PTTK). Coagulation is delayed by deficiencies of coagulation factors and by the presence of inhibitors of coagulation, such as heparin and lupus anticoagulants. The approximate reference ranges and causes of abnormalities are shown in Box 25.3. If both the PT and APTT are prolonged, this indicates either deficiency or inhibition of the final common pathway (which includes factors X, V, prothrombin and fibrinogen) or global coagulation factor deficiency involving more than one factor, as occurs in disseminated intravascular coagulation (DIC; pp. 199 and 988). Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be a chemical (heparins) or an antibody (most often a lupus anticoagulant, but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 984.

Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin, arachidonic acid and ADP, agglutination in response to ristocetin or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate, adenosine diphosphate and their ratio to each other (ATP/ADP).

In disseminated intravascular coagulation (DIC), platelets and coagulation factors are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with consumption of fibrinogen and generation of fibrin degradation products (D-dimers). Note, however, that fibrinogen is an acute phase protein that may also be elevated in inflammatory disease (p. 67).

Monitoring anticoagulant therapy

The International Normalised Ratio (INR) is validated only to assess the therapeutic effect of coumarin anticoagulants, including warfarin. INR is the ratio of the patient’s PT to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by comparison with an international reference standard material). Concentrations of the direct oral anticoagulants (DOAcs) cannot be accurately assessed from the PT or the APTT, with which they have a variable and generally poor correlation, but can be measured using appropriately calibrated specific assays.

Monitoring of heparin therapy is, on the whole, required only with unfractionated heparins (UFH). Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of approximately 1.5–2.5. Many laboratories now prefer to measure UFH activity by an appropriately calibrated anti-Xa assay. Low-molecular-weight heparins have such a predictable dose response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (glomerular filtration rate less than 30mL/min). When monitoring is indicated, an anti-Xa assay is used.

### Thrombotic disorders

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active venous thrombosis in some patients (see Fig. 9.6).

A variety of tests exist that may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (thrombophilia) (Box 25.4). Examples of possible indications for testing are given in Box 25.5. In most patients, the results of these tests do not affect clinical management (p. 984) but they may influence the duration of anticoagulation (e.g. antiphospholipid antibodies, p. XXX), justify family screening in inherited thrombophilies (p. 986), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 959). Anticoagulants can interfere with some of these assays. For example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant. Heparin interferes with antithrombin and lupus anticoagulant assays and the DOACs all affect the measurement of lupus anticoagulant as well as other specific
coagulation assays. Therefore these tests, when required, should be performed when the patient is not taking anticoagulants or, if required, during temporary discontinuation to facilitate accurate measurement.

Box 25.6 lists some considerations specific to all haematological investigations in old age.

### Presenting problems in blood disease

#### Anaemia

Anaemia refers to a state in which the level of haemoglobin in the blood is below the reference range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must

*N.B. International Normalised Ratio (INR) is used only to monitor coumarin therapy and is not a coagulation screening test. Ranges are approximate and may vary between laboratories. (DIC = disseminated intravascular coagulation)*

---

**25.4 Investigation of possible thrombophilia**

**Full blood count**

**Plasma levels**

- Antithrombin
- Protein C
- Protein S (free)
- Antiphospholipid antibodies, lupus anticoagulant, anticoagulant antibody/ant-β, GPI

**Thrombin/antithrombin time (for dysfibrinogenemia)**

**Genetic testing**

- Factor V Leiden
- Prothrombin G20210A
- JAK-2 V617F mutation
- CALR mutations
- MPL 515 mutation

**Flow cytometry**

- Screen for GPI-linked cell surface proteins (CD14, 16, 55, 59), deficient in paroxysmal nocturnal haemoglobinuria

(CD = cluster of differentiation; GPI = glycoprotein 1; GPI = glycerol phosphatidyl inositol)

---

**25.5 Possible indications for thrombophilia testing**

- Venous thrombosis <45 years
- Recurrent venous thrombosis
- Family history of unprovoked or recurrent thrombosis
- Combined arterial and venous thrombosis
- Venous thrombosis at an unusual site: Cerebral venous thrombosis
- Hepatic vein (Budd–Chiari syndrome)
- Portal vein, mesenteric vein, splenic vein

*Antiphospholipid antibodies should be sought where clinical criteria for antiphospholipid syndrome (APS) are fulfilled (p. 986). Thrombophilia testing may explain the diagnosis without necessarily affecting management and this limits the clinical value of such an approach.*
**25.6 Haematological investigations in old age**

- Blood cell counts and film components: not altered in general by ageing alone, although haemoglobin concentrations fall with increasing age.
- Ratio of bone marrow cells to marrow fat: falls.
- Neutrophils: maintained throughout life, although leucocytes may be less readily mobilised by bacterial invasion in old age.
- Lymphocytes: functionally compromised by age due to a T-cell-related defect in cell-mediated immunity.
- Clotting factors: no major changes, although mild congenital deficiencies may be first noticed in old age.
- Erythrocyte sedimentation rate (ESR): raised above the reference range, but usually in association with chronic or subacute disease. In truly healthy older people, the ESR range is very similar to that in younger people (see Ch. 4).
- Clonal haematopoeisis. Myeloid gene panels are more likely to demonstrate clonal haematoipoiesis of indeterminate potential (CHIP) based on acquired gene mutations in the blood cells of older patients. This may occur as frequently as 20% of people aged over 80 years despite having normal blood counts.

---

**25.7 Causes of anaemia**

**Decreased or ineffective marrow production**

- Lack of iron, vitamin B₁₂ or folate
- Hypoplasia/myelodysplasia
- Invasion by malignant cells
- Renal failure
- Anaemia of chronic disease

**Normal marrow production but increased removal of cells**

- Blood loss
- Haemolysis
- Hypersplenism

---

Clinical assessment

- **Iron deficiency anaemia** (p. 950) is the most common type of anaemia worldwide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia is a common cause of anaemia in pre-menopausal females, so women should always be asked about menstrual periods.
- A **dietary history** should assess the intake of iron, B₁₂ and folate, which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; see also Chs 22 and 33).
- A **past medical history** may reveal a disease that is known to be associated with anaemia, such as rheumatoid arthritis (anaemia of inflammation (AI)), or previous surgery (e.g. resection of the stomach or small bowel, which may lead to malabsorption of iron and/or vitamin B₁₂).
- A **family history** and ethnic background may raise suspicion of haemolytic anaemias, such as the haemoglobinopathies, oxidative enzymopathies and membranopathies. Pernicious anaemia, an autoimmune disorder, may also run in families, but is not associated with a clear Mendelian pattern of inheritance.
- A **drug history** may reveal the ingestion of drugs that cause or worsen blood loss (e.g. anticoagulants, anti-platelet drugs and anti-inflammatory drugs), haemolysis (e.g. sulphonamides and anti-malarial drugs) or aplasia (e.g. chloramphenicol, mercaptopurine).

On examination, as well as the general physical findings of anaemia shown on page, there may be specific findings related to the aetiology of the anaemia; for example, a right iliac fossa mass due to an underlying caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B₁₂ deficiency may be associated with neurological signs, including peripheral neuropathy, dementia and signs of subacute combined degeneration of the cord (Box 28.82). Sickle-cell anaemia (p. 960) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia may be multifactorial and the lack of specific symptoms and signs does not rule out silent pathology.

**Investigations**

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:

- A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease, also known as the anaemia of inflammation (ACD/AI) (Fig. 25.10).
- A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia or sometimes ACD/AI (Fig. 25.10).
- A high MCV (macrocytic anaemia) suggests vitamin B₁₂ or folate deficiency or myelodysplasia (Fig. 25.11).

Specific types of anaemia and their management are described later in this chapter.

**High haemoglobin**

Patients with a persistently raised haematocrit (Hct) (> 0.52 males, > 0.48 females) for more than 2 months should be investigated. ‘True’ polycythaemia (or absolute erythrocytosis) indicates an excess of red cells, while ‘relative’, ‘apparent’ or ‘low-volume’ polycythaemia is due to a decreased plasma volume. Causes of polycythaemia are shown in Box 25.8. These involve increased erythropoiesis in the bone marrow, either due to a primary increase in marrow activity, or in response to increased erythropoietin (Epo) levels in chronic hypoxaemia, or due to inappropriate secretion of Epo. Some athletes improperly use Epo to increase oxygen-carrying capacity and thus enhance their physical performance.

Apparent erythrocytosis with a raised Hct, normal red cell mass (RCM) and reduced plasma volume may be associated with hypertension, smoking, alcohol and diuretic use (Gaisböck syndrome).

**Clinical assessment and investigations**

Males and females with Hct values of over 0.60 and over 0.56, respectively, can be assumed to have an absolute erythrocytosis. A clinical history and examination including measurement of oxygen saturation will identify most patients with polycythaemia secondary to hypoxia. The presence of hypertension, smoking, excess alcohol consumption and/or diuretic use is consistent with low-volume polycythaemia (Gaisböck syndrome). In polycythaemia rubra vera (PRV), the acquired V617F mutation is found in the JAK2 gene (a kinase) in over 90% of cases; in the remainder, mutations in exon 12 of the same gene may be identified. Patients with PRV have an increased risk of arterial thromboses, particularly stroke, and venous thromboembolism. They may also have aquagenic pruritus (itching after exposure to water), hepatosplenomegaly and gout (due to high red cell turnover).

If JAK2 mutations are absent and there is no obvious secondary cause, a measurement of red cell mass is required to confirm an absolute erythrocytosis, followed by further investigations to exclude hypoxia, and causes of inappropriate erythropoietin secretion.

**Leucopenia (low white cell count)**

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types (usually neutrophils or lymphocytes). Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 939).

**Neutropenia**

A reduction in neutrophil count (usually <1.5 × 10⁹/L but dependent on age and race) is called neutropenia. The main causes are listed in Box 25.9 and Fig. 25.12. Drug-induced neutropenia is not uncommon (Box 25.10). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than 0.5 × 10⁹/L considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy is not commenced. Management is discussed on page 269.

**Lymphopenia**

This is an absolute lymphocyte count of less than 1 × 10⁹/L. The causes are shown in Box 25.9. Although minor reductions may be asymptomatic, deficiencies in cell-mediated immunity may result in infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as Epstein-Barr virus (EBV), human papillomavirus (HPV) and human herpesvirus 8 (HHV-8)). Lymphopenia without any obvious cause is common with advancing age.

**Leucocytosis (high white cell count)**

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see Box 25.9). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not increase the total white cell count (WCC) above the upper limit of normal and will be apparent only if the “differential” of the white count is examined.

**Neutrophilia**

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends on age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils, but also earlier forms, such as metamyelocytes, can be found in the blood. The causes of a neutrophilia are shown in Box 25.9.

**Eosinophilia**

A high eosinophil count of more than 0.5 × 10⁹/L is usually secondary to infection (especially parasites; Ch. 13), allergy (e.g. eczema, asthma, reactions to drugs; Ch. 4), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see Box 25.9). Usually, such eosinophilia is short-lived.

In the rarer primary disorders, there is a persistently raised, often clonal, eosinophilia, e.g. in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hyper eosinophilic syndrome (HES). Specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing rearrangements of platelet-derived growth factor receptors α and β or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib. Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); evaluation of eosinophilia therefore includes not only the identification of any underlying cause and its appropriate treatment, but also assessment of any related organ damage.

**Lymphocytosis**

An lymphocytosis is an increase in circulating lymphocytes above that expected for the patient’s age. In adults, this is greater than 3.5 × 10⁹/L. Infants and children have higher counts; age-related reference ranges should be consulted. Causes are shown in Box 25.9; the most common is viral infection.

**Lymphadenopathy**

Enlarged lymph glands may be an important indicator of haematological disease, but they are not uncommon in reaction to infection or inflammation (Box 25.11). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 921. Nodes that enlarge in response to local infection or inflammation (“reactive nodes”) usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation or primary malignancy in the appropriate drainage area:

- the scalp, ear, mouth and throat, face, teeth or thyroid for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes
**25.9 How to interpret white blood cell results**

**Neutrophils**

- Infection: bacterial, fungal
- Trauma: surgery, burns
- Infarction: myocardial infarct, pulmonary embolus, sickle-cell crisis
- Inflammation: gout, rheumatoid arthritis, ulcerative colitis, Crohn’s disease
- Malignancy: solid tumours, Hodgkin lymphoma
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Physiological: exercise, pregnancy

**Neutropenia**

- Infection: viral, bacterial (e.g. Salmonella), protozoal (e.g. malaria)
- Drugs: see Box 25.10
- Autoimmune: connective tissue disease
- Alcohol
- Bone marrow infiltration: leukaemia, myelodysplasia
- Congenital: Kostmann syndrome
- Constitutional: African Caribbean and Middle Eastern descent

**Eosinophils**

- Allergy: hay fever, asthma, eczema
- Infection: parasitic
- Drug hypersensitivity: e.g. gold, sulphonamides
- Vascular: e.g. eosinophilic granulomatosis with polyangiitis (Churg–Strauss), granulomatosis with polyangiitis (Wegener’s)
- Connective tissue disease: polyarteritis nodosa
- Malignancy: solid tumours, lymphomas
- Primary bone marrow disorders: myeloproliferative disorders, hypereosinophilic syndrome (HES), acute myeloid leukaemia

**Basophils**

- Myeloproliferative disease: polycythaemia vera, chronic myeloid leukaemia
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn’s disease

**Monocytes**

- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn’s disease
- Malignancy: solid tumours, chronic myelomonocytic leukaemia

**Lymphocytes**

- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: glucocorticoids, cytotoxics
- Congenital: severe combined immunodeficiency
- Human immunodeficiency virus (HIV) infection

- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)

**Sarcoidosis**

**Amyloidosis**

**Drugs**

- Phenytoin

Generalised lymphadenopathy may be secondary to infection, often viral, connective tissue disease or extensive skin disease (dermatopathic lymphadenopathy), but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats that may require a change of nightclothes are associated with haematological malignancies, particularly lymphoma.
Initial investigations in lymphadenopathy include an FBC (to detect evidence of infection, inflammation or haematological disease such as leucocytosis, thrombocytosis or lymphopenia), measurement of erythrocyte sedimentation rate (ESR) and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision biopsy of a representative node is indicated to obtain a histological diagnosis. Increasingly, such lymph node biopsies are carried out under image guidance using ultrasound or CT scanning, rather than formal surgical excision biopsy. However, the quality of such specimens is variable and can be difficult to interpret, especially if they are small.

**Splenomegaly**

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extramedullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections, or vascular congestion as a result of portal hypertension (Box 25.12).

*Causes of massive splenomegaly.

Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating and early satiety due to stomach compression. Splenic infarction produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation should focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen, which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis, as might a bone marrow biopsy in splenic lymphomas. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, pooling and destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leucoerythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease (p. 8665) may be appropriate. If all investigations are unhelpful, splenectomy may be diagnostic, but is rarely carried out in these circumstances.

**Bleeding**

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, the coagulation factors or von Willebrand factor, or occasionally to excessive fibrinolysis, which is most commonly observed following therapeutic thrombolysis (Ch. 16).

**Clinical assessment**

‘Screening’ blood tests (see Box 25.3) do not reliably detect all causes of pathological bleeding (e.g. von Willebrand disease, scurvy, certain anticoagulant and anti-platelet drugs and the causes of purpura listed in Box 25.13) and should not be used indiscriminately. A careful clinical evaluation is the key to diagnosis of bleeding disorders (p. 980). It is important to consider the following:

- **Site of bleeding.** Bleeding into muscle and joints, along with retroperitoneal and intracranial haemorrhage, indicates a likely defect in coagulation factors. Purpura, prolonged bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent bleeds at a single site suggest a local structural abnormality rather than coagulopathic bleeding.
- **Duration of history.** It may be possible to assess whether the disorder is congenital or acquired.
- **Precipitating causes.** Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.
- **Surgery.** Ask about operations. Dental extractions, tonsillectomy and circumcision are stressful tests of the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis; delayed haemorrhage is more suggestive of a coagulation defect. However, in post-surgical

### 25.13 Causes of non-thrombocytopenic purpura

- Senile purpura
- Factitious purpura
- Henoch–Schönlein purpura (Ch. 26)
- Vasculitis (Ch. 26)
- Paraproteinaemias
- Purpura fulminans, e.g. in disseminated intravascular coagulation secondary to sepsis
patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than coagulopathic bleeding.

- **Family history.** While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history, and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- **Drugs.** Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some ‘herbal’ remedies may result in a bleeding diathesis.

Clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 25.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction. Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple, but become yellow as haemoglobin is degraded. Retropertitoneal bleeding presents with a flank or peri-umbilical haematoma. Telangectasia of lips and tongue points to hereditary haemorrhagic telangectasia (p. 970). Joints should be examined for evidence of haemarthroses. A full examination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

**Investigations**

Screening investigations and their interpretation are described on page 930. If the patient has a history that is strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed.

**Thrombocytopenia (low platelet count)**

A reduced platelet count may arise by one of two mechanisms:

- decreased or abnormal production (bone marrow failure and hereditary thrombocytopenias)
- increased consumption following release into the circulation (immune-mediated, DIC or sequestration).

Spontaneous bleeding does not usually occur until the platelet count falls below 20 × 10⁹/L, unless their function is also compromised. Purpura and spontaneous bruising are characteristic, but there may also be oral, nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia (<10 × 10⁹/L) may result in retinal haemorrhage and potentially fatal intracranial bleeding, but this is rare.

Investigations are directed at the possible causes listed in Box 25.14. A blood film is the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts below 10 × 10⁹/L, or to clinical situations with actual or predicted serious haemorrhage.

**Thrombocytosis (high platelet count)**

The most common reason for a raised platelet count is that it is reactive to another process, such as infection, inflammation, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 25.15). The presenting clinical features are usually those
of the underlying disorder and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets, lack of splenomegaly and the presence of an associated underlying disorder. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time (reactive thrombocytosis gets better with resolution of the underlying cause).

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia and some forms of myelodysplasia. As with PPF, patients with essential thrombocythaemia may present with thrombosis or, rarely, bleeding. Stroke, transient ischaemic attacks, amaurosis fugax, digital ischaemia or gangrene, aquagenic pruritus, splenomegaly and systemic upset are also features. Patients with myeloproliferative disorders may also present with features such as aquagenic pruritus, splenomegaly and systemic upset.

Pancytopenia

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells as a consequence of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in Box 25.16. A bone marrow aspirate and trephine are usually required to establish the diagnosis.

Infection

Infection is a major complication of haematological disorders. It relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 268 and 933).

### 25.15 Causes of a raised platelet count

**Reactive thrombocytosis**
- Acute and chronic inflammatory disorders
- Infection
- Malignant disease

**Clonal thrombocytosis**
- Primary thrombocythaemia
- Polycythaemia rubra vera
- Chronic myeloid leukaemia
- Myelofibrosis

**Tissue damage**
- Haematological anaemias
- Post-splenectomy
- Post-haemorrhage

**Myelodysplastic syndromes (MDSs)**
- MDS with ring sideroblasts and thrombocytosis
- MDS with isolated deletion of 5q

---

### 25.16 Causes of pancytopenia

**Bone marrow failure**
- Hypoplastic/aplastic anaemia (p. 978): inherited, idiopathic, viral, drugs

**Bone marrow infiltration**
- Acute leukaemia
- Myeloma
- Lymphoma
- Carcinoma
- Haemophagocytic syndrome
- Myelodysplastic syndromes

**Ineffective haematopoiesis**
- Megaloblastic anaemia
- Acquired immunodeficiency syndrome (AIDS)

**Peripheral pooling/destruction**
- Hypersplenism: portal hypertension, Felty syndrome, malaria, myelofibrosis
- Systemic lupus erythematosus

---

### Principles of management of haematological disease

#### Blood components and transfusion

Blood transfusion from an unrelated donor to a recipient inevitably carries some risk, including adverse immunological interactions between the host and infused blood (see below), and transmission of infectious agents. Although there are many compelling clinical indications for blood component transfusion, there are also many clinical circumstances where transfusion is conventional, but the evidence for its effectiveness is limited. In these settings, allogeneic transfusion may be avoided by following protocols that recommend the use of low haemoglobin thresholds for red cell transfusion, perioperative blood salvage and antifibrinolytic drugs.

#### Blood components

Blood components are prepared from whole blood or specific blood constituents collected from individual donors and include red cells, platelets, plasma and cryoprecipitate (Box 25.17).

Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes of human plasma obtained from many people and treated to reduce the risk of transmissible infection. Examples include:

- **Coagulation factors.** Concentrates of factors VIII and IX are used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease. Coagulation factors made by recombinant DNA technology are now preferred due to perceived lack of infection risk but plasma-derived products are still used in many countries.
- **Immunoglobulins.** Intravenous immunoglobulin G (IVIgG) is administered as regular replacement therapy to reduce infective complications in patients with primary and secondary immunodeficiency. A short, high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 981) and Guillain–Barré syndrome (Ch. 29). IVIgG can cause acute reactions and must be infused strictly according to the manufacturer’s product information. There is a risk of renal dysfunction in susceptible patients and in these circumstances immunoglobulin products containing low or no sucrose are preferred. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster (Ch. 13). Anti-Rheusus D immunoglobulin is used in pregnancy to prevent haemolytic disease of the newborn (see Box 25.19).
- **Human albumin.** This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid, but it is no more effective and is more expensive than crystalloid solutions. Human albumin 20% solution may be used in the management of hypoproteinaemic oedema in nephrotic syndrome (Ch. 19) and refractory ascites in chronic liver disease (Ch. 24). It is hyperoncotic and expands plasma volume by more than the amount infused.

Blood components and their uses are summarised in Box 25.17.

#### Blood donation

A safe supply of blood components depends on a well-organised system with regular donation by healthy individuals who have no excess risk of infections transmissible in blood (Fig. 25.14). Blood donations are obtained by either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis, the donor’s blood is drawn via a closed system into a machine that separates the components by centrifugation and collects the desired fraction into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B virus (HBV), hepatitis C virus (HCV), HIV and human T-cell lymphotrophic virus (HTLV) nucleic acid

</tr>
</tbody>
</table>

| Platelet concentrate | Maintain platelet count >50 × 10^9/L, or in multiple or central nervous system trauma >100 × 10^9/L<br> If ongoing bleeding, order when platelets <100 × 10^9/L to allow for delivery time<br> Each adult dose has a minimum of 2.4 × 10^11 platelets, which raises platelet count by 40 × 10^9/L unless there is consumptive coagulopathy, e.g. disseminated intravascular coagulation | Thrombocytopenia, e.g. in acute leukaemia<br> Maintain platelet count >10 × 10^9/L if not bleeding<br> Maintain platelet count >20 × 10^9/L if minor bleeding or at risk (sepsis, concurrent use of antibiotics, abnormal coagulation)<br> Increase platelet count >50 × 10^9/L for minor invasive procedure (e.g. lumbar puncture, gastroscopy and biopsy, insertion of indwelling lines, liver biopsy, laparotomy) or in acute, major blood loss<br> Increase platelet count >100 × 10^9/L for operations in critical sites such as brain or eyes |

| Fresh frozen plasma | Dilutional coagulopathy with a PT prolonged >50% is likely after replacement of 1–1.5 blood volumes with red cell concentrate<br> Give initially in (at least) a ratio of 1 FFP:2 red cell concentrate; order 15–20mL/kg and allow for thawing time. Further doses only if bleeding continues and guided by PT and APTT | Replacement of coagulation factor deficiency<br> If no virally inactivated or recombinant product is available<br> Thrombotic thrombocytopenic purpura<br> Plasma exchange (using virus-inactivated plasma if available) is frequently effective |

| Cryoprecipitate | Aim to keep fibrinogen >1.5 g/L. Pooled units (of 10 donations) will raise fibrinogen by 1 g/L | von Willebrand disease and haemophilia<br> If virus-inactivated or recombinant products are not available |

*Whole blood is an alternative to red cell concentrate. ABO compatibility with recipient essential. Pooled plasma can be treated with solvent and detergent or single units treated with methylene blue as an additional viral inactivation step. Virus-inactivated plasma is indicated for large-volume exposure, as in treatment of thrombotic thrombocytopenic purpura. (APTT = activated partial thromboplastin time; FFP = fresh frozen plasma; Hb = haemoglobin; PT = prothrombin time)*

and/or antibodies. Platelet concentrates may be tested for bacterial contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for *Trypanosoma cruzi* (Chagas’ disease; Ch. 13) is necessary in areas of South America and the United States where infection is prevalent. Tests for West Nile virus have been required in the United States and UK since this agent became more prevalent. Components for use in specific patient groups are prepared from hepatitis E virus-negative donors in the UK, and plasma donated in the UK is not used at present for producing pooled plasma derivatives in view of concerns about transmission of variant Creutzfeldt–Jakob disease (vCJD; Ch. 28).

### Red cell incompatibility

Red blood cell membranes contain numerous cell surface molecules that are potentially antigenic (see Fig. 25.4). The ABO and Rhesus D antigens are the most important in routine transfusion and antenatal practice.

### ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The ABO gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain, which has three common alleles: A, B and O. The O allele encodes an inactive enzyme, leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by four amino acids and hence attach different sugars to the end of the chain. Individuals are tolerant to their own ABO antigens, but do not suppress B-cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 25.18). They are, therefore, capable of mounting an humoral immune response to these ‘foreign’ antigens.

### ABO-incompatible red cell transfusion

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the
Fig. 25.14 Blood donation, processing and storage. ¹Platelet apheresis involves circulating the donor’s blood through a cell separator to remove platelets before returning other blood components to the donor. ²In the UK, plasma for fractionation is imported as a precautionary measure against variant Creutzfeldt–Jakob disease (vCJD). (HIV = human immunodeficiency virus; HTLV = human T-cell lymphotropic virus)

</tbody>
</table>

recipient’s IgM anti-A, anti-B or anti-AB binds to the transfused red cells. This activates the full complement pathway (Ch. 4), creating pores in the red cell membrane and destroying the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin (IL)-1 and IL-8, and stimulate degranulation of mast cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension, which may, in turn, cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20%–30% of
ABO-incompatible transfusions cause some degree of morbidity, and 5%–10% cause or contribute to a patient’s death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

The Rhesus D blood group and haemolytic disease of the newborn

About 15% of populations of predominantly European descent are Rhesus-negative; that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 25.4). In other populations (e.g. in Chinese and Bengalis), only 1%–5% are Rhesus-negative. RhD-negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD-positive red cells enter the circulation of an RhD-negative individual, IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via fetomaternal haemorrhage, or following transfusion. If a woman is sensitised, during a subsequent pregnancy anti-RhD antibodies can cross the placenta; if the fetus is RhD-positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD-negative female who may subsequently become pregnant should never be transfused with RhD-positive blood.

In RhD-negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of RhD antibodies (Box 25.19).

HDN can also be caused by other alloantibodies against red cell antigens, usually after previous pregnancies or transfusions. These antigens include Rhc, RhC, RhE, Rh, and the Kell, Kidd and Duffy antigen systems. HDN can also occur if there is fetomaternal ABO incompatibility, most commonly seen in a group O mother with a group A fetus. The fetus is generally less severely affected by ABO incompatibility than by RhD. Rhc or Kell antigen mismatch and the incompatibility is often picked up coincidentally after birth.

Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease (TA GVHD). The latter occurs when there is sharing of a human leucocyte antigen (HLA) haplotype between donor and recipient, which allows transfused lymphocytes to engraft, proliferate and recognise the recipient as foreign, resulting in acute GVHD (p. 946). Prevention is by gamma- or X-ray irradiation of blood components before their administration to prevent lymphocyte proliferation. Those at risk of TA GVHD who must receive irradiated blood components include patients with congenital T-cell immunodeficiencies or Hodgkin lymphoma, patients with aplastic anaemia receiving immunosuppressive therapy with antithymocyte globulin (ATG), recipients of haematopoietic stem cell transplants or of blood from a family member, neonates who have received an intrathecal transfusion, and patients taking T-lymphocyte-suppressing drugs, such as fludarabine and other purine analogues.

Transfusion-transmitted infection

Over the past 30 years, HBV, HIV-1 and HCV have been identified and effective tests introduced to detect and exclude infected donations. Where blood is from ‘safe’ donors and correctly tested, the current risk of a donated unit being infectious is very small. In the UK, the estimated chance that a unit of blood from a ‘safe’ donor might be infected with one of the viruses for which blood is tested is approximately 1 in 25 million units for HIV-1, less than 1 in 100 million for HCV and 1 in 1.2 million for HBV. However, some patients who received transfusions before these tests were available suffered serious consequences from infection; this serves as a reminder to avoid non-essential transfusion since it is impossible to exclude the emergence of new or currently unrecognised transfusion-transmissible infection. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

Variant CJJD is a human prion disease linked to bovine spongiform encephalitis (BSE, Ch. 28). The risk of a recipient acquiring the agent of vCJD from a transfusion is uncertain, but of 16 recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 1 other had postmortem immunohistological features of infection.

Bacterial contamination of a blood component – usually platelets – is extremely rare (there have been no proven cases in the UK in recent years) but can result in severe bacterenaemia/sepsis in the recipient.

Safe transfusion procedures

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative. Their consent to proceed with transfusion should be obtained and the documentation documented. Some patients, e.g. Jehovah’s Witnesses, may refuse transfusion and require specialisation management to survive profound anaemia following blood loss.

Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a ‘group and screen’ procedure or a ‘cross-match’. In the group and screen procedure, the red cells from the patient’s blood sample are tested to determine the ABO and RhD type, and the patient’s serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen can be selected. The patient’s sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cells with the patient’s serum. Full cross-matching takes about 45 minutes, if no red cell antibodies are present, but may require hours if a patient has multiple antibodies.

Blood can be supplied by ‘electronic issue’, without the need for compatibility cross-matching, if the laboratory’s computer system shows that the patient’s ABO and RhD groups have been identified and confirmed on two separate occasions and their antibody screen is negative. This allows group-specific units to be issued quickly and safely, for elective and emergency transfusion.

Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Most incompatible transfusions result from failure to adhere to standard procedures for correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2019, the annual incidence of transfusion of an incorrect
blood component is approximately 15 per 100000 units transfused. Every hospital where blood is transfused should have a written transfusion policy used by all staff who order, check, or administer blood products (Fig. 25.15). Management of suspected transfusion reactions is shown in Fig. 25.16.

## Transfusion in major haemorrhage

The successful management of a patient with major haemorrhage requires frontline clinical staff to be trained to recognise significant blood loss early and to intervene before shock is established. Hospitals should have local major haemorrhage protocols and all clinical staff must be familiar with their content. Good team working and communication are essential to prevent poor clinical outcome, suboptimal or inappropriate transfusion practice and component wastage. Fresh frozen plasma (FFP) should be given as part of initial resuscitation in (at least) a 1:2 ratio with red cell concentrate (RCC) until coagulation results are available. If the patient is bleeding, a ratio of FFP to RCC of 1:1 should be given until laboratory results are available and use of cryoprecipitate should be considered. Once the bleeding is under control, further FFP transfusion should be guided by laboratory results with transfusion triggers of PT and/or APTT above 1·5 times normal for a standard dose of FFP (15–20 mL/kg). Cryoprecipitate should be given if the fibrinogen level falls below 1·5 g/L. Platelets should be kept above 50 x 10^9/L; to allow for delivery time, platelets should be requested if there is ongoing bleeding and the platelet count has fallen below 100 x 10^9/L. Blood component use in major haemorrhage is summarised in Box 25.17 and key points in transfusion medicine in Box 25.20.

### Anti-cancer drugs

#### Cytotoxic chemotherapy

Many haematological malignancies are sensitive to the effects of cytotoxic chemotherapy drugs and, as such, they remain the mainstay of treatment for most haematological cancers (Box 25.21; see also Fig. 7.2). There is a wide range of drugs available that work by damaging DNA or disrupting cellular metabolism, in such a way that natural apoptosis mechanisms, such as TP53, are activated and the cell dies. Despite cancer cells being more sensitive, chemotherapy is largely non-specific and kills some normal cells as well as cancer cells. This leads to common side-effects of treatment, such as transient bone marrow failure, hair loss, mucositis and infertility. The supportive care of patients undergoing chemotherapy is critical in overcoming these side-effects. It is this supportive care, including blood product support, antibiotics, antifungal drugs, growth factors and antiemetics, that has allowed specialist haematology units to achieve the best possible results from intensive chemotherapy: for example, when treating acute leukaemia.

The basic principles of chemotherapy include combining several non-cross-reacting drugs in a regimen that kills a fixed proportion of cancer cells with a given dose. Several cycles of the combination are given to achieve gradual reduction of the tumour burden, to induce remission and, in some instances, to produce a cure (Ch. 7).

#### 25.20 Key points in transfusion medicine

| A restrictive strategy for red cell transfusion (Hb < 70 g/L) is at least as effective as a liberal strategy (<100 g/L). |
| The majority of reports in haemovigilance schemes such as SHOT relate to errors in the process of transfusion. |
| Although transfusion-transmitted infection is a major concern for patients receiving transfusion, it is rare. |
| In patients with trauma or burns or those who have had surgery, there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions. |
| It is recommended that transfusion should be carried out overnight only in unavoidable circumstances. |

*SHOT = Serious Hazards of Transfusion*

---

**Fig. 25.15** Bedside procedures for safe blood transfusion. The patient’s safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.

Monoclonal antibodies

In recent years, chemotherapy has been improved by the addition of treatments that are more targeted to the cancer cell, particularly monoclonal antibodies; for example, rituximab (anti-CD20) has been added to CHOP (cyclophosphamide doxorubicin, vincristine, prednisolone) and other regimens. This has significantly improved the outcome in a range of CD20-positive B-cell lymphomas, including diffuse large B-cell lymphoma, follicular lymphoma and mantle cell lymphoma. As well as “naked” monoclonal antibodies that kill malignant cells by engaging antibody-dependent cytotoxic T cells or complement, chemotherapy drugs can also be linked to a monoclonal antibody to allow targeting of the chemotherapy drug to the specific cancer cell. Examples of such antibody–drug conjugates (ADCs) or ‘payload’ antibodies include the linking of the intercalating antibiotic calicheamicin to anti-CD33 (gemtuzumab ozogamicin) in the treatment of acute myeloid leukaemia (see Fig. 25.27) and to anti-CD22 (inotuzumab ozogamicin) in the treatment of acute lymphoblastic leukaemia (see Fig. 25.28).

Small molecule targeted therapies

Small molecules targeted at the mechanisms causing cancer are replacing cytotoxic chemotherapy in some disease situations. The most successful of these to date are tyrosine kinase inhibitors targeting BCR-ABL in chronic myeloid leukaemia, which have transformed the treatment of this disease over the last 20 years (see Fig. 25.29). This is a rapidly growing area of medicine and now includes inhibitors of B-cell signalling in chronic lymphocytic leukaemia and lymphomas (see Fig. 25.30) and drugs that target mutated gene products, such as FMS-like tyrosine kinase 3-internal tandem duplication (FLT3-ITD) in acute myeloid leukaemia. More details of specific therapies are given later in the chapter.

Immunotherapy

This includes cellular immunotherapy (see below) and non-cellular immunotherapy such as antibody and antibody-conjugate mediated cytotoxicity as outlined above and checkpoint inhibitor therapy as described in Chapter 7. Checkpoint inhibitor therapy has, to date, proved less useful in haematological malignancies than in solid tumours. This might be because haematological malignancies tend to have less acquired mutations to stimulate T-cell attack than do solid tumours.

Haematopoietic stem cell transplantation

Transplantation of haematopoietic stem cells (HSCT) has offered the only hope of ‘cure’ in a variety of haematological and non-haematological disorders (Box 25.22). As standard treatment improves, the indications for HSCT are being refined and extended, although its use remains most common in haematological malignancies. The type of HSCT is defined according to the donor and source of stem cells:

- In allogeneic HSCT, the stem cells come from a donor – either a related donor (usually an HLA-identical sibling) or a closely HLA-matched unrelated donor (VUD).
- In an autologous transplant, the stem cells are harvested from the patient and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from the bone marrow or, most commonly nowadays, from the blood.

Allogeneic HSCT

Healthy bone marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably ‘conditioned’. The conditioning treatment (chemotherapy with or without radiotherapy) is ‘myeloablative’ or, increasingly, ‘non-myeloablative’. Myeloablative conditioning destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient’s haematopoietic tissues. Reduced intensity conditioning (non-myeloablative) relies on intense immunosuppression to provide ‘immunological space’ for transplanted stem cells. The infused donor cells ‘home’ to the marrow, engratify and produce enough erythrocytes, granulocytes and platelets for the patient’s needs after about 2–4 weeks. During this period of aplasia, patients are at risk of infection and bleeding, and require intensive supportive care as described on page 966. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, particularly in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor’s immune system can recognise residual recipient malignant cells and destroy them. This immunological ‘graft-versus-disease’ effect is a powerful tool against many haematological tumours and can be boosted post-transplantation by the infusion of T cells taken from the donor: so-called donor lymphocyte infusion (DLI).

Considerable morbidity and mortality are associated with HSCT. The best results are obtained in younger patients (<40 years) with minimal residual disease, who have an HLA-identical sibling donor. However, reduced-intensity conditioning (RIC) has enabled treatment of older or less fit patients, in whom the majority of haematological malignancies occur. In this form of transplantation, rather than using very intensive myeloablative conditioning, which causes morbidity from organ damage, relatively low doses of chemotherapy drugs, such as fludarabine and cyclophosphamide or busulfan, are used in combination with antibodies such as alemtuzumab (which targets CD52 on mature lymphoid cells) or anti-thymocyte globulin (ATG) to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the ‘graft-versus-disease’ effect, which may be boosted by the elective use of donor T-cell infusions post-transplant. Such transplants have produced long-term remissions in some patients with acute leukaemia and myelodysplastic syndromes aged 40–70 years, who would not previously have been considered for a myeloablative allograft.

Complications

These are outlined in Boxes 25.23 and 25.24. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications, such as infection and GVHD, and there remains a significant risk of the haematological malignancy relapsing. The long-term survival for patients undergoing allogeneic HSCT in acute leukaemia is around 50%.

Graft-versus-host disease

GVHD is caused by the cytotoxic activity of donor T lymphocytes that become sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppres- sant drugs, including methotrexate, ciclosporin, alemtuzumab or ATG. Severe presentations are very difficult to control and, despite high-dose glucocorticoids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with glucocorticoids and prolonged immunosuppression with, for example, ciclosporin. Chronic GVHD results in an increased infection risk. However, associated with chronic GVHD is the ‘graft-versus-disease’ effect and a lower relapse rate of the underlying malignancy.

Autologous HSCT

This procedure can also be used in haematological malignancies. The patient’s stem cells from blood or marrow are first harvested and frozen when their disease is in remission. After conditioning myeloablative therapy, the autologous stem cells are reinfused into the blood stream in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. This is an effective way of safely delivering high-dose chemotherapy to chemo-sensitive cancers. Autologous
25.21 Examples of commonly used cytotoxic chemotherapy drugs in haematology

**Alkylating agents (cross-link double-stranded DNA by adding an alkyl group)**
- Cyclophosphamide
- Melphalan
- Chlorambucil

**Anthracyclines (intercalate between base pairs in the DNA molecule)**
- Daunorubicin
- Doxorubicin
- Idarubicin

**Antimetabolites (inhibit DNA and RNA synthesis)**
- Cytosine arabinoside
- Fludarabine
- Methotrexate

**Vinca alkaloids (cause disruption of tubulin)**
- Vincristine
- Vinblastine

**Topoisomerase II inhibitors (prevent DNA repair)**
- Etoposide
- Daunorubicin
- Mitoxantrone

**Monoclonal antibodies**

Naked antibodies engaging antibody-dependent cytotoxic T cell or complement
- **Anti-CD20**
  - Rituximab,
  - Obinotuzumab

**Anti-CD19**
- Blinatumumab – bi-specific T-cell engager (BiTE)

**Antibody-delivered cytotoxicity (ADC or ‘payload antibodies’)**
- **Anti-CD33 linked to calicheamicin**
- Gemtuzumab ozogamicin
- **Anti-CD22 linked to calicheamicin**
- Inotuzumab ozogamicin
- **Anti-CD30 linked to monomethyl auristatin E**
- Brentuximab vedotin

**Targeted small molecules**

**Inhibitors of tyrosine kinases (TKIs)**
- Imatinib, dasatinib, nilotinib, ponatinib and bosutinib in CML
- Midostaurin and gilteritinib in FLT-3-positive AML

**Inhibitors of B-cell signalling in lymphoid malignancies**
- Inhibitors of Bruton’s tyrosine kinase in CLL, ibrutinib and acalabrutinib
- Inhibitors of PI3 kinase in CLL and follicular lymphoma,idelalisib

*For sites of action of these agents in the cell cycle, see Fig. 7.2.*

AML = acute myeloid leukaemia; CD = cluster of differentiation; CML = chronic myeloid leukaemia; FLT-3 = FMS-like tyrosine kinase 3; PI3 = phosphatidylinositol-3-

**HSCT may be used as consolidation chemotherapy for disorders that do not primarily involve the haematopoietic tissues, or for patients in whom very good remissions have been achieved. The common indications are lymphomas and myeloma. The preferred source of stem cells for autologous transplants is peripheral blood (PBSC). These stem cells engraft more quickly, marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Thus autologous HSCT carries a lower procedure-related mortality rate than allogeneic HSCT at around 1%–5%, but there is a higher rate of recurrence of malignancy because the anti-malignancy effect is solely dependent on the conditioning chemotherapy with no ‘graft-versus-disease’ effect. There is ongoing interest in using autologous HSCT to treat severe autoimmune diseases. The theory is that the patient’s immune system is ‘reset’ to not attack host tissues. Early success in multiple sclerosis has led to current randomised controlled trials in this area.**

### Alternative cellular therapies

While HSCT remains a major cellular therapy for a range of malignant and some non-malignant haematological conditions, newer cell-based treatments have been recently introduced into practice. These include donor T cells primed to respond to specific viruses, including cytomegalovirus (CMV) and Epstein–Barr Virus (EBV). Immunocompromised patients, such as those post solid organ or haematopoietic transplantation, can suffer from reactivation of latent CMV or EBV infection and develop life-threatening complications, e.g. pneumonitis (CMV) and post-transplant lymphoproliferative disease (EBV). Primed donor T cells can be used to treat these
Anticoagulant and antithrombotic therapy

There are numerous indications for anticoagulant and antithrombotic medications (Box 25.25). The guiding principles are outlined here, but management in specific indications is discussed elsewhere in the book. Broadly speaking, antiplatelet medications are of greater efficacy in the prevention of arterial thrombosis and of less value in the prevention of venous thromboembolism (VTE). Thus, antiplatelet agents, such as aspirin, clopidogrel and, increasingly, ticagrelor, are the drugs of choice in acute coronary events (Ch. 16) and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in VTE (p. 985) and management of atrial fibrillation (Ch. 16). In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and antiplatelet drugs is used.

A wide range of anticoagulant and antithrombotic drugs is used in clinical practice. These drugs and their modes of action are given in Box 25.26 and Fig. 25.18. Newer agents allow predictable anticoagulation without the need for frequent monitoring and dose titration. Although warfarin remains an option for oral anticoagulation, newer oral anticoagulants (dabigatran, rivaroxaban, edoxaban and apixaban), which can be given at fixed doses with predictable effects and no need for monitoring, have now been approved for the prevention of periparative VTE, the treatment of established VTE and the prevention of cardioembolic stroke in patients with atrial fibrillation.

Heparins

Unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) act as anticoagulants by binding a specific pentasaccharide...
sequence to antithrombin. This enhances the avidity of anti-thrombin for its substrates, which are the activated proteases of the coagulation pathway such as Xa and thrombin (see Fig. 25.18). Fondaparinux is a synthetic pentasaccharide, which also binds antithrombin and has similar properties to LMWH. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH, but have several advantages:

- LMWHs are nearly 100% bioavailable and so produce reliable dose-dependent anticoagulation.
- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients with very low body weight and with a glomerular filtration rate below 30 mL/min).
- LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or twice-daily subcutaneous administration required for UFH.
- While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.

UFH is, however, more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice (Box 25.27).

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 25.25. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous, except when rapid reversibility is required. UFH is useful in patients with a high risk of bleeding, e.g. those who have peptic ulceration or who may require urgent surgery. It is also favoured in the treatment of life-threatening thromboembolism, e.g. major pulmonary embolism with significant hypoxaemia, hypotension and right-sided heart strain. In this situation, UFH is started with a loading intravenous dose of 80 U/kg, followed by a continuous infusion of 18 U/kg/hr initially. The level of anticoagulation should be assessed by the APTT after 6 hours and, if satisfactory, twice daily thereafter. It is usual to aim for a patient APTT that is 1.5–2.5 times the control time of the test. Monitoring of UFH treatment by APTT is not without difficulties and other assays, such as the specific anti-Xa assay calibrated for measurement of UFH, provides more accurate guidance.

**Heparin-induced thrombocytopenia**

Heparin-induced thrombocytopenia (HIT) is a rare complication of heparin therapy, caused by induction of anti-heparin/PEG antibodies that bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with a paradoxical thrombocytopenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin. Some adenovirus vector-based SARS-CoV-2 RNA vaccines have been associated with a similar condition characterised by venous thrombosis (often cerebral) and paradoxical thrombocytopenia.

**Clinical features**

Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of more than 30% from baseline. The count may still be in the reference range. The patient may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin
necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms, such as shivering, following heparin injections. Patients who have received heparin in the preceding 100 days and who have preformed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

**Investigations**

The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the Thrombocytopenia
- the Timing of the fall in platelet count
- the presence of new Thrombosis
- the likelihood of another Cause for the thrombocytopenia.

Individuals at low risk need no further test. Those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using an anti-PF4 enzyme-linked immunosorbent assay (ELISA).

**Management**

Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant that does not cross-react with the antibody should be substituted. Argatroban (a direct thrombin inhibitor) and danaparoid (a heparin analogue) are licensed for use in the UK. Fonaparinux is not licensed for this indication but can also be used. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poorer prognosis.

### Coumarins

Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K-dependent post-translational carboxylation of factors II (prothrombin), VII, IX and X in the liver (see Fig. 25.6D). This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (see Box 25.3). Recommended target INR values for specific indications are given in Box 25.25.

Warfarin anticoagulation typically takes more than 3–5 days to become established, even using loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regimen in this situation is to give 10mg warfarin on the first and second days, with 5mg on the third day; subsequent doses are titrated against the INR. Patients without an urgent need for anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supertherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication and while treatment of deep vein thrombosis (DVT) or preparation for cardioversion may require a finite duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- a narrow therapeutic window
- metabolism that is affected by many factors
- numerous drug interactions.

Drug interactions are common through protein binding and metabolism by the cytochrome P450 system. Inter-individual differences in warfarin doses required to achieve a therapeutic INR are mostly accounted for by naturally occurring polymorphisms in the CYP2C9 and the VKORC1 genes (which predict the metabolism and function of warfarin, respectively) and dietary intake of vitamin K.
**25.28 How to assess risks of anticoagulation**

**Contraindications**
- Recent surgery, especially to eye or central nervous system
- Pre-existing haemorrhagic state, e.g. advanced liver disease, haemophilia, thrombocytopenia
- Pre-existing structural lesions, e.g. peptic ulcer
- Recent cerebral or gastrointestinal haemorrhage
- Uncontrolled hypertension
- Cognitive impairment
- Frequent falls

**Bleeding risk score**
- Several bleeding risk scores exist for different indications for anticoagulation
- The validation of most bleeding risk scores has been poor
- Many risk factors for thrombosis are also risk factors for bleeding
- HAS BLED is the best validated score for patients with atrial fibrillation.
- Following anticoagulant-related bleeding, reassessment of bleeding and thrombosis risk is indicated
- In many cases, patients benefit from recommencing anticoagulants after bleeding

Major bleeding is the most common serious side-effect of warfarin and occurs in 1%–2% of patients each year. Fatal haemorrhage, which is most commonly intracranial, occurs in about 0.25% per annum. There are scoring systems that predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box 25.28). There are also some specific contraindications to anticoagulation (Box 25.28). Management of warfarin includes strategies for over-anticoagulation and for bleeding:

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or intravenously (1–2.5 mg), especially if the INR is greater than 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K intravenously (IV). Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly IV, combined with coagulation factor replacement (see Box 25.27). This should optimally be a prothrombin complex concentrate (30–50 U/kg) that contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

**Direct oral anticoagulants**

The direct oral anticoagulants (DOACs) are specific inhibitors of key proteases in the common pathway and offer an alternative to coumarins in the management of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation. Dabigatran inhibits thrombin while rivaroxaban, apixaban and edoxaban inhibit Xa (see Fig. 25.19). The key features of these drugs include the fact that they are efficacious in fixed oral doses, have a short half-life of around 10 hours, achieve peak plasma levels 2–4 hours after oral intake, have very few drug interactions and are all more dependent on renal function for their excretion. An initial perceived drawback was the lack of specific reversal agents for these drugs, but the monoclonal antibody idarucizumab is now available for the reversal of dabigatran and andexanet alfa, a site-inactivated Xa molecule, has recently been licensed for the reversal of apixaban and rivaroxaban (see Box 25.27).

DOACs are now licensed for the prevention of VTE following high-risk orthopaedic surgery (except edoxaban), the acute management and prevention of recurrence of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation with risk factors. Dosing is standard across a range of conditions, but is affected by extremes (low and high) of body weight and impaired renal function. The general perception is that in these indications they are at least as efficacious as dose-adjusted coumarin and probably associated with less clinically significant bleeding.

---

**Anaemias**

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs. 25.10 and 25.11).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 25.19). While in the marrow compartment, red cell precursors undergo cell division driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease/anaemia of inflammation.

In megaloblastic anaemia, the biochemical consequence of vitamin B12 or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow, such as myelodysplasia. In these states, cells haemoglobinise normally, but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer that freely exchanges with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised – e.g. in haemolysis – this may also increase the MCV.

**Iron deficiency anaemia**

This occurs when iron losses or physiological requirements exceed absorption.

**Blood loss**

The most common explanation in men and post-menopausal women is gastrointestinal blood loss (Ch. 23). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angioidysplastic lesions. Worldwide, hookworm and schistosomiasis are the most common causes of gut blood loss (Ch. 13). Gastrointestinal blood loss may be exacerbated by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries, one-third of pre-menopausal women have low iron stores, but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

**Malabsorption**

A dietary assessment should be made in all patients to ascertain their iron intake (Ch. 22). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 25.20). Achlorhydria in older people or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 819).

**Physiological demands**

At times of rapid growth, such as infancy and puberty, iron requirements increase and may outstrip absorption. In pregnancy, iron is diverted to the fetus, the placenta and the increased maternal red cell mass, and is lost with bleeding at parturition (Box 25.29).
Fig. 25.19 Factors that influence the size of red cells in anaemia. In microcytosis, the MCV is <76 fL. In macrocytosis, the MCV is >100 fL. (MCV = mean cell volume; RBC = red blood cell)

Fig. 25.20 The regulation of iron absorption, uptake and distribution in the body. The transport of iron is regulated in a similar fashion to enterocytes in other iron-transporting cells such as macrophages.
Investigations

Confirmation of iron deficiency

Serum ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 25.30). A subnormal level is most often due to iron deficiency or, very rarely, hypothyroidism or vitamin C deficiency. Ferritin levels can be raised in liver disease and in the acute phase response; in these conditions, a ferritin level of up to 100 μg/L may still be compatible with low bone marrow iron stores.

Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response, but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, the acute phase response and nephrotic syndrome, but raised by pregnancy and the oral contracep- tive pill. A transferrin saturation (i.e. iron/TIBC x 100) of less than 16% is consistent with iron deficiency, but is less specific than a low ferritin measurement.

All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. When iron stores are low, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease, when a raised level indicates iron deficiency. In difficult cases, it may still be necessary to examine a bone marrow aspirate for iron stores.

Investigation of the cause

This will depend on the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or radiological studies. Current guidelines suggest exclusion of coeliac disease by antibody testing at an early stage of investigation of iron deficiency. In the tropics, stool and urine should be examined for parasites (Box 13.10).

Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not indicated and oral iron replacement is appropri- ate. Ferrous sulphate 200 mg 3 times daily (195 mg of elemental iron per day) is adequate and should be continued for 3–6 months to replete iron stores. Many patients suffer gastrointestinal side-effects with fer- rous sulphate, including dyspepsia and altered bowel habit. When this occurs, reduction in dose or another alternative oral preparation should be tried. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine, where it cannot be absorbed.

The haemoglobin should rise by around 10 g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-adherence, continued blood loss, malabsorption or an incorrect diagnosis. Patients with malabsorp- tion, chronic gut disease or inability to tolerate any oral preparation may need parenteral iron therapy. Previously, iron dextran or iron sucrose was used, but new preparations of ferric isomaltose and ferric carboxylate have fewer allergic effects and are preferred. Doses required can be calculated based on the patient’s starting haemoglobin and body weight. Observation for anaphylaxis following an initial test dose is recommended.

Anaemia of chronic disease

Anaemia of chronic disease (ACD), also known as anaemia of inflamma- tion (AI), is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with haemoglobin in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low, but iron stores are normal or increased, as indicated by the ferritin or storable marrow iron.

Pathogenesis

It has become clear that the key regulatory protein that accounts for the findings characteristic of ACD/Al is hepcidin, which is produced by the liver (see Fig. 25.20). Hepcidin production is induced by pro-inflam- matory cytokines, especially IL-6. Hepcidin binds to ferroportin on the membrane of iron-exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood. The iron remains trapped inside the cells in the form of ferritin, levels of which are there- fore normal or high in the face of significant anaemia. Inhibition or blockade of hepcidin is a potential target for treatment of this form of anaemia.

Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 25.30 summarises the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A posi- tive response occurs in true iron deficiency, but not in ACD. Measures that reduce the severity of the underlying disorder generally help to improve the ACD. Trials of higher-dose intravenous iron are under way to try to bypass the hepcidin-induced blockade.

Megaloblastic anaemia

This results from a deficiency of vitamin B₁₂ or folate acid, or from distur- bances in folic acid metabolism. Folate is an important substrate of, and vitamin B₁₂ a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B₁₂ or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The end result is cells with arrested nuclear maturation, but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early-nucleated red cell precursors and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis...
characteristic of other forms of haemolysis (see Box 25.31). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of ‘giant’ metamyelocytes with a large ‘sausage-shaped’ nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, a pancytopenia may be present in the peripheral blood.

Vitamin B<sub>12</sub> deficiency, but not folate deficiency, is associated with pathological disease in up to 40% of cases, although advanced neurological disease due to B<sub>12</sub> deficiency is now uncommon in the developed world. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesiae and ataxia of gait. The clinical and diagnostic features of megaloblastic anaemia are summarised in Boxes 25.31 and 25.32, and the neurological features of B<sub>12</sub> deficiency in Box 25.33.

### Vitamin B<sub>12</sub>

#### Vitamin B<sub>12</sub> absorption

The average daily diet contains 5–30 μg of vitamin B<sub>12</sub>, mainly in meat, fish, eggs and milk – well in excess of the 1 μg daily requirement. In the stomach, gastric enzymes release vitamin B<sub>12</sub> from food and at gastric pH it binds to a carrier protein termed R protein. The gastric parietal cells produce intrinsic factor, a vitamin B<sub>12</sub>-binding protein that optimally binds vitamin B<sub>12</sub> at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B<sub>12</sub> released from the diet switches from the R protein to intrinsic factor. Bile also contains vitamin B<sub>12</sub> that is available for reabsorption in the intestine. The vitamin B<sub>12</sub>-intrinsic factor complex binds to specific receptors in the terminal ileum, and vitamin B<sub>12</sub> is actively transported by the enterocytes to plasma, where it binds to transcobalamin II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The liver stores enough vitamin B<sub>12</sub> to last for approximately 3 years and this, together with the enterohpatic circulation, means that vitamin B<sub>12</sub> deficiency takes years to become manifest, even if all dietary intake is stopped or severe B<sub>12</sub> malabsorption supervenes.

Blood levels of vitamin B<sub>12</sub> (cobalamin) provide a reasonable indication of tissue stores, are usually diagnostic of deficiency and remain the first-line tests for most laboratories. Additional tests have been evaluated, including measurement of methylmalonic acid, holotranscobalamin and plasma homocysteine levels, but do not add much in most clinical situations. Levels of cobalamins fall in normal pregnancy. Reference ranges vary between laboratories, but levels below 150 ng/L are common and, in the last trimester, 5%–10% of women have levels below 100 ng/L. Spuriously low B<sub>12</sub> values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B<sub>12</sub> assays.

### Causes of vitamin B<sub>12</sub> deficiency

#### Dietary deficiency

This occurs only in strict vegans, but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B<sub>12</sub> levels, but are not tissue vitamin B<sub>12</sub>-deficient.

#### Gastric pathology

Release of vitamin B<sub>12</sub> from food requires normal gastric acid and enzyme secretion and this is impaired by hypochlorhydria in older patients or
following gastric surgery. Total gastrectomy invariably results in vitamin \( B_12 \) deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin \( B_12 \) injections. After partial gastrectomy, vitamin \( B_12 \) deficiency only develops in 10%–20% of patients by 5 years; an annual injection of vitamin \( B_12 \) should prevent deficiency in this group. Patients may develop \( B_12 \) deficiency after certain types of bariatric surgery (see Ch. 22).

Pernicious anaemia

This is an organ-specific autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin \( B_12 \) is absorbed. Pernicious anaemia has an incidence of 25/100,000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto’s thyroiditis, Graves’ disease, vitiligo or Addison’s disease; Ch. 20) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of \( B_12 \) deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases, but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely, but a positive result is not diagnostic. The Schilling test, involving measurement of absorption of radio-labelled \( B_12 \) after oral administration before and after replacement of intrinsic factor, has fallen out of favour with the availability of autoantibody tests, greater caution in the use of radioactive tracers and limited availability of intrinsic factor.

Small bowel pathology

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin \( B_12 \) from R protein to intrinsic factor. This usually results in slightly low vitamin \( B_12 \) values, but no tissue evidence of vitamin \( B_12 \) deficiency. Inflammatory disease of the terminal ileum, such as Crohn’s disease, may impair the absorption of vitamin \( B_12 \)-intrinsic factor complex, as may surgery on that part of the bowel. Motilility disorders or hypogammaglobulinaemia can result in bacterial overgrowth and the ensuing competition for free vitamin \( B_12 \) can lead to deficiency. A small number of people heavily infected with the fish tapeworm (Ch. 13) develop vitamin \( B_12 \) deficiency.

### Folate

#### Folate absorption

Folates are produced by plants and bacteria; hence dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50μg, but excess cooking destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is an enterohepatic circulation. Total body stores of folate are small and deficiency can occur in a matter of weeks.

#### Folate deficiency

The causes and diagnostic features of folate deficiency are shown in Boxes 25.34 and 25.35. Eclamptous older people or psychiatric patients are particularly susceptible to dietary deficiency and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis worldwide and is more likely in the context of twin pregnancies, multiparity and hyperemesis gravidarum. Serum folate measurement is very sensitive to dietary intake; a single folate-rich meal can normalise it in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant therapy can reduce it in the absence of megaloblastosis. For this reason, red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

### Management of megaloblastic anaemia

If a patient with a severe megaloblastic anaemia is very ill and treatment must be started before vitamin \( B_12 \) and red cell folate results are available, that treatment should always include both folic acid and vitamin \( B_12 \). The use of folic acid alone in the presence of vitamin \( B_12 \) deficiency may result in worsening of neurological features.

Rarely, if severe angina or heart failure is present, transfusion can be used. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 U of red cells with diuretic cover may be given.

#### Vitamin \( B_12 \) deficiency

Vitamin \( B_12 \) deficiency is treated with hydroxycobalamin. In cases of malabsorption, 1000μg IM for 6 doses 2 or 3 days apart, followed by maintenance therapy of 1000μg every 3 months for life, is recommended. In the presence of neurological involvement, a dose of 1000μg on alternate days until there is no further improvement, followed by maintenance as above, is recommended. In dietary deficiency oral \( B_12 \) replacement will suffice. The reticulocyte count will peak by the 5th–10th day after starting replacement therapy. The haemoglobin will rise by 10g/L every week until normalised. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. A sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

#### Folate deficiency

Oral folic acid (5mg daily for 3 weeks) will treat acute deficiency and 5mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at
risk and reduces the risk of fetal neural tube defects (Box 22.29). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. haemolytic anaemias).

**Haemolytic anaemia**

Haemolysis indicates that there is shortening of the normal red cell lifespan of 120 days. There are many causes, as shown in Fig. 25.21. To compensate, the bone marrow may increase its output of red cells six- to eightfold by increasing the proportion of red cells produced, expanding the volume of active marrow, and releasing reticulocytes prematurely. Anaemia occurs only if the rate of destruction exceeds this increased production rate.

There are some general features of haemolysis and other specific features that help to identify the reason for haemolysis. Results of investigations that establish the presence of haemolysis are shown in Box 25.36. Red cell destruction overloads pathways for haemoglobin breakdown in the liver (p. 864), causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobilinogen from the gut results in an increase in urinary urobilinogen (pp. 870 and 924). Red cell destruction releases LDH into the serum. The bone marrow compensation results in a reticulocytosis and sometimes nucleated red cell precursors appear in the blood. Increased proliferation of the bone marrow can result in a thrombocytosis, neutrophilia and, if marked, immature

---

**Fig. 25.21 Causes and classification of haemolysis.**

- **Inherited causes.**
  - Red cell membrane abnormality
    - Hereditary spheroctosis
    - Hereditary elliptocytosis
  - Red cell enzyme deficiency
    - Glucolysis pathway, e.g. PK
    - Hexose monophosphate shunt, e.g. G6PD
    - Pyrimidine 5' nucleotidase
  - Haemoglobin
    - Deficiency, e.g. thalassaemias
    - Abnormality, e.g. sickle-cell disease

- **Acquired causes.**
  - Immune
    - Autoantibodies
      - Warm antibodies
        - Primary idiopathic
          - Secondary
            - Primary idiopathic
              - Secondary
                - Infection, e.g. mycoplasma, EBV, syphilis
                - Lymphoproliferative disorders, e.g. lymphoma
          - Chemical/physical
            - Oxidative drugs, e.g. dapsone, maloprim
            - Copper (Wilson's disease)
            - Burns
            - Drowning
        - Cold antibodies
          - Primary idiopathic
            - Secondary
              - Red cell antigen-induced
                - Transfusion reaction
                - Haemolytic disease of the newborn
    - Mechanical
      - Prosthetic valves
      - Microangiopathic, e.g. DIC, HUS, TTP
      - March haemoglobinuria
  - Non-immune
    - Chemical/physical
      - Oxidative drugs, e.g. dapsone, maloprim
      - Copper (Wilson's disease)
      - Burns
      - Drowning
    - Acquired abnormal membrane
      - Paroxysmal nocturnal haemoglobinuria

---

**25.36 Investigation results indicating active haemolysis**

**Hallmarks of haemolysis**
- ↓ Haemoglobin
- ↑ Unconjugated bilirubin
- ↑ Lactate dehydrogenase
- ↑ Reticulocytes
- ↑ Urinary urobilinogen

**Additional features of intravascular haemolysis**
- ↓ Haptoglobin
- ↑ Methaemalbumin
- Positive urinary haemosiderin
- Haemoglobinuria
granulocytes in the blood, producing a leucoerythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis:

- spherocytes are small, dark red cells that suggest autoimmune haemolysis or hereditary spherocytosis
- sickle cells suggest sickle-cell disease
- red cell fragments indicate microangiopathic haemolysis
- bite cells (normal-sized red cells that look as if they have been partially eaten) suggest oxidative haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 25.21).

**Extravascular haemolysis**

Physiological red cell destruction occurs in the reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the plasma. In most haemolytic states, haemolysis is predominantly extravascular.

To confirm the haemolysis, patients' red cells can be labelled with $^{51}$ chromium. When re-injected, they can be used to determine red cell survival; when combined with body surface radioactivity counting, this test may indicate whether the liver or the spleen is the main source of red cell destruction. However, this is seldom performed in clinical practice.

**Intravascular haemolysis**

Less commonly, red cell lysis occurs within the blood stream due to membrane damage by complement (ABO transfusion reactions, paroxysmal nocturnal haemoglobinuria), infections (malaria, Clostridium perfringens), mechanical trauma (heart valves, DIC) or oxidative damage (e.g. enzymopathies such as glucose-6-phosphate dehydrogenase deficiency, which may be triggered by drugs such as dapsone and maloprothrombin). When intravascular red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an $\alpha$-globulin produced by the liver which binds free haemoglobin, resulting in a fall in its levels during active haemolysis. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin, which binds to albumin in turn forming methaemalbumin, which can be detected spectrophotometrically in Schumm's test. Methaemoglobin is degraded and any free haem is bound to a second binding protein called haemopexin. If all the protective mechanisms are saturated, free haemoglobin may appear in the urine (haemoglobinuria). When fulminant, this gives rise to black urine, as in severe falciparum malaria infection (Ch. 13). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give rise to haemosiderinuria, which is always indicative of intravascular haemolysis (see Box 25.30).

**Causes of haemolytic anaemia**

These can be classified as inherited or acquired (see Fig. 25.21).

- **Inherited** red cell abnormalities resulting in chronic haemolytic anaemia may arise from pathologies of the red cell membrane (hereditary spherocytosis or elliptocytosis), haemoglobin (haemoglobinopathies), or protective enzymes that prevent cellular oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD).
- **Acquired** causes include auto- and alloantibody-mediated destruction of red blood cells and other mechanical, toxic and infective causes.

**Red cell membrane defects**

The structure of the red cell membrane is shown in Fig. 25.4. The basic structure is a cytoskeleton “stapled” on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity; the red cell diameter is 8 $\mu$m, but the narrowest capillaries in the circulation are in the spleen, measuring just 2 $\mu$m in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell shape (see Box 25.2) and reduced red cell survival due to extravascular haemolysis.

**Hereditary spherocytosis**

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1:5000 in high-income countries, but this may be an under-estimate since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 25.4). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, a reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or co-inheritance of a second defect involving a different protein. These cases tend to present earlier in life with symptomatic, sometimes transfusion-dependent anaemia.

The clinical course may be complicated by crises:

- **Haemolytic crisis** occurs when the severity of haemolysis increases; this is rare, and usually associated with infection.
- **Megaloblastic crisis** follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- **Aplastic crisis** occurs in association with parvovirus (erythrovirus) infection (p. 280). Parvovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

**Investigations**

The patient and other family members should be screened for features of compensated haemolysis (see Box 25.36). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes, but the direct Coombs test (Fig. 25.22) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions, but is limited by lack of sensitivity and specificity. More specific flow cytometric tests detecting binding of eosin-5-maleimide to red cells are recommended in borderline cases.

**Management**

Folic acid prophylaxis (5mg daily) should be given for life. In severe cases, consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications for splenectomy include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed where possible until after 6 years of age in view of the subsequent risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 25.37.

Acute, severe haemolytic crises require transfusion support, but cross-matched blood must be transfused slowly as haemolytic transfusion reactions may occur (see Fig. 25.16).

**Hereditary elliptocytosis**

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional abnormality of one or more anchor proteins in the red cell membrane, e.g. alpha spectrin or protein 4.1
**25.37 Management of the splenectomised patient**

- Vaccinate with pneumococcal, *Haemophilus influenzae* type B, meningococcal group C and influenza vaccines at least 2–3 weeks before elective splenectomy. Vaccination should be given after emergency surgery but may be less effective.
- Pneumococcal re-immunisation should be given at least 5-yearly and influenza annually. Vaccination status must be documented.
- Lifelong prophylactic penicillin V (500 mg twice daily) is recommended. In penicillin-allergic patients, consider a macrolide.
- Patients should be educated regarding the risks of infection and methods of prophylaxis.
- A card or bracelet should be carried to alert health professionals to the risk of overwhelming sepsis.
- In sepsis, patients should be resuscitated and given intravenous antibiotics to cover pneumococcus, *Haemophilus* and meningococcus, according to local resistance patterns.
- The risk of cerebral malaria is increased in the event of infection.
- Animal bites should be promptly treated with local dissection and antibiotics to prevent serious soft tissue infection and sepsis.

(see Fig. 25.4). Inheritance may be autosomal dominant or recessive. Hereditary elliptocytosis is less common than hereditary spherocytosis in Western countries, with an incidence of 1/10,000, but is more common in equatorial Africa and parts of South-east Asia. The clinical course is variable and depends on the degree of membrane dysfunction caused by the inherited molecular defect(s); most cases present as an asymptomatic blood film abnormality, but occasional cases result in neonatal haemolysis or a chronic compensated haemolytic state. Management of the latter is the same as for hereditary spherocytosis.

A characteristic variant of hereditary elliptocytosis occurs in South-East Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The blood film is often very abnormal and immediate differential diagnosis is broad.

**Red cell enzymopathies**

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume while protecting itself from the oxidative stress presented by oxygen carriage. ATP is generated by glycolysis, while the hexose monophosphate shunt produces nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends on the importance of the steps affected and the presence of alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis precipitated by episodic oxidative stress, while those in the glycolysis pathway result in shortened red cell survival and chronic haemolysis.

**Glucose-6-phosphate dehydrogenase deficiency**

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzynopathy, affecting 10% of the world’s population, with a geographical distribution that parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits that are encoded by a gene on the X chromosome. The deficiency therefore affects males and rare homozygous females (Ch. 3), but it is carried by females. Carrier heterozygous females are usually only affected in the neonatal period or in the presence of skewed X-inactivation.

Over 400 subtypes of G6PD are described. The most common types associated with normal activity are the B+ enzyme present in most populations of European descent and 70% of those of African Caribbean origin, and the A+ variant present in 20% of African Caribbeans. The two common variants associated with reduced activity are the A- variety in approximately 10% of African Caribbeans, and the Mediterranean or B- variety in those of European origin. In East and West Africa, up to 20% of males and 4% of females (homozygotes) are affected and have enzyme levels of about 15% of normal. The deficiency in European and East Asian populations is more severe, with enzyme levels as low as 1%.
### 25.38 Glucose-6-phosphate dehydrogenase deficiency

#### Clinical features
- Acute drug-induced haemolysis (e.g.): Analgesics: aspirin, phenacetin.
  - Antimalarials: primaquine, quinine, chloroquine, pyrimethamine.
  - Antibiotics: sulphonamides, nitrofurantoin, ciprofloxacin.
  - Miscellaneous: quinidine, probenecid, vitamin K, dapsone.
- Chronic compensated haemolysis.
- Infection or acute illness.
- Neonatal jaundice: may be a feature of the B⁻ enzyme.
- Favaism, i.e. acute haemolysis after ingestion of broad beans (Vicia fava).

#### Laboratory features
**Non-spherocytic intravascular haemolysis during an attack**
- The blood film will show:
  - Bite cells (red cells with a "bite" of membrane missing).
  - Blister cells (red cells with surface blistering of the membrane).
  - Irregularly shaped small cells.
  - Polychromasia reflecting the reticulocyteosis.
  - Denatured haemoglobin visible as Heinz bodies within the red cell cytoplasm with a supravital stain such as methyl violet.

**G6PD level**
- Can be indirectly assessed by screening methods that usually depend on the decreased ability to reduce dyes.
- Direct assessment of G6PD is made in those with low screening values.
- Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result.

Clinical features and investigation findings are shown in Box 25.38. Management aims to stop the intake of any precipitant drugs or foods and treat any underlying infection. Favaism due to the consumption of fava beans is the classically described precipitant of haemolysis in patients with G6PD deficiency. Acute transfusion support may be life-saving.

#### Pyruvate kinase deficiency
This is the second most common red cell enzyme defect. It results in deficiency of ATP production and a chronic haemolytic anaemia. It is inherited as an autosomal recessive trait. The extent of anaemia is variable; the blood film shows characteristic "prickle cells" that resemble holly leaves. Enzyme activity is only 5%–20% of normal. Transfusion support may be necessary during periods of haemolysis.

#### Pyrimidine 5’ nucleotidase deficiency
The pyrimidine 5’ nucleotidase enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see Box 25.25), associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

#### Autoimmune haemolytic anaemia
This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or IgM, or more rarely IgE or IgA. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular (in the reticulo-endothelial system). Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:

- **Cold antibodies** bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. To be clinically relevant, they must act within the range of normal body temperatures. They account for the other 20% of cases.

### Warm autoimmune haemolysis
The incidence of warm autoimmune haemolysis is approximately 1/100,000 population per annum; it occurs at all ages, but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions (see Fig. 25.21B).

#### Investigations
There is evidence of haemolysis, spherocytes and polychromatasia on the blood film. The diagnosis is confirmed by the direct Coombs or antiglobulin test (see Fig. 25.22). The patient’s red cells are mixed with Coombs reagent, which contains antibodies against human IgG/IgM complement. If the red cells have been coated by antibody in vivo, the Coombs reagent will induce their agglutination and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is for Rhesus antigens and most often anti-D; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies. Around 10% of all warm autoimmune haemolytic anaemias are Coombs test-negative.

#### Management
If the haemolysis is secondary to an underlying cause, this must be treated and any implicated drugs stopped. It is usual to treat patients initially with prednisolone (1 mg/kg orally). A response is seen in 70%–80% of cases, but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticuloocyte levels. Once the haemoglobin has normalised and the reticuloocyte resolved, the glucocorticoid dose can be reduced slowly over several weeks. Glucocorticoids probably work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production. Transfusion support may be required for life-threatening problems, such as the development of heart failure or rapid unabated falls in haemoglobin. The least incompatible blood should be used, but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to glucocorticoids or can only be stabilised by large doses, then second-line therapy with the anti-CD20 monoclonal antibody rituximab should be considered. Failure to respond to rituximab can be followed by consideration of treatment with a range of immunomodulatory/ immunosuppressive agents or splenectomy. Pharmacological agents include azathioprine, ciclosporin, danazol and mycophenolate mofetil. Splenectomy is associated with a good response in 50%–60% of cases. The operation can be performed laparoscopically with reduced morbidity. There are concerns about all modes of third-line therapy as long-term immunosuppression carries a risk of malignancy, while splenectomy is associated with an excess of severe infection due to the capsule organisms pneumococcus and meningococcus (see Box 25.40).

#### Cold agglutinin disease
This is mediated by antibodies, usually IgM, which bind to the red cells at low temperatures and cause them to agglutinate. It may cause intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.
Chronic cold agglutinin disease

This typically affects older adult patients and may be associated with an underlying low-grade B-cell lymphoma. It causes a low-grade intra-vascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (so-called acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder, exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously high because the automated analysers detect red cell aggregates as single cells. Monoclonal IgM usually has anti-I or, less often, anti-i specificity. Treatment is primarily by transfusion support, but may also be directed at any underlying lymphoma. Patients must keep extremities warm, especially in winter. Some patients respond to rituximab. Fludarabine can be added in if a clonal abnormality is detected. For patients requiring blood transfusion, the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood must be administered via a blood-warming. All patients should receive folic acid supplementation.

Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneu- moniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children, in association with viral or bacterial infection. An IgG antibody binds to red cells in the peripheral circulation, but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath–Landsteiner antibody and has specificity against the P antigen on the red cells.

### Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is caused by antibodies against non-self red cells. It has two main causes, occurring after:

- unmatched blood transfusion (see Fig. 25.16)
- maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, see Box 25.19).

### Non-immune haemolytic anaemia

#### Endothelial damage

Disruption of red cell membrane may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- Mechanical heart valves. High flow through incompetent valves or peri-prosthetic leaks through the suture ring holding a valve in place result in shear stress damage.
- March haemoglobinuria. Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- Thermal injury. Severe burns cause thermal damage to red cells, characterised by fragmentation and the presence of microspherocytes in the blood.
- Microangiopathic haemolytic anaemia. Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (Ch. 18), thrombotic thrombocytopenic purpura and disseminated intravascular coagulation (p. 988).

#### Infection

*Plasmodium falciparum* malaria (p. 319) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever because of the associated haemoglobinuria. *Clostridium perfringens* sepsis (p. 271), usually in the context of ascending cholangitis or necrotising fasciitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecinthase that destroys the red cell membrane.

### Chemicals or drugs

Dapsone and sulfasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrites and nitrobenzene derivatives may all cause haemolysis.

### Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired, non-malignant clonal expansion of haematopoietic stem cells deficient in glycosylphosphatidylinositol (GPI) anchor protein. GPI anchors several key molecules to cells and its absence results in clinical outcomes that reflect this, causing intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. This happens because key defence mechanisms that protect cells from complement-mediated lysis (CD55 and CD59) are GPI-anchored to red cells under normal circumstances. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine, which has a characteristic red-brown colour. The disease is associated with an increased risk of venous and arterial thrombosis in unusual sites, such as the liver or abdomen. PNH clones are also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (see later). Management is supportive with transfusion and folate supplements and prophylaxis or treatment of thrombosis. Standard care now includes the anti-complement C5 monoclonal antibodies eculizumab and ravulizumab. This has been shown to be effective in reducing haemolysis, transfusion requirements and thrombotic risk. The C5 inhibitory antibodies both carry a risk of infection, particularly for *Neisseria meningitidis*, and all treated patients must be vaccinated against this organism.

### Haemoglobinopathies

These disorders are caused by mutations affecting the genes encoding the globin chains of haemoglobin. Normal haemoglobin is composed of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, including in the fetus, so severe mutations in these may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (Hbf–αα/γγ) has two gamma chains, while the predominant adult haemoglobin (HbA-αα/ββ) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A2 (HbA,-αα/ββ, usually less than 2%) is made from birth. The geographical distribution of the common haemoglobinopathies is shown in Fig. 25.23. The haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

#### Qualitative abnormalities – abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobinins) there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but the more recently described ones are known by names that are usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell anaemia. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

#### Quantitative abnormalities – thalassaemias

In quantitative abnormalities (the thalassaemias), there are mutations causing a reduced rate of production of one or other of the globin chains,
altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, while in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival due to haemolysis.

**Sickle-cell anaemia**

Sickle-cell disease results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait (Ch. 3). Homozygotes only produce abnormal beta chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disease. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in sickle-cell trait; although this was previously thought of as asymptomatic, it may be associated with an increased risk of sudden and cardiovascular death in young adults.

**Epidemiology**

The heterozygote frequency is over 20% in tropical Africa (see Fig. 25.23). In African American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the effects of falciparum malaria in early childhood; the high prevalence in equatorial Africa can thus be explained by the survival advantage it confers in areas where falciparum malaria is endemic. However, homozygous patients with sickle-cell anaemia do not have correspondingly greater resistance to falciparum malaria.

**Pathogenesis**

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as ‘tactoids’. These distort the red cell membrane and produce characteristic sickle-shaped cells (Fig. 25.24). The polymerisation is reversible when re-oxygenation occurs. The distortion of the red cell membrane, however, may become permanent and the red cell ‘irreversibly sickled’. The greater the concentration of sickle-cell haemoglobin in the individual cell, the more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus the abnormal haemoglobin C variant participates in polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

**Clinical features**

Sickling is precipitated by hypoxia, acidosis, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the microcirculation. This results in a number of acute syndromes, termed ‘crises’, and chronic organ damage (see Fig. 25.24):

- **Painful vaso-occlusive crisis.** Plugging of small vessels in the bone produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebral bone in adults. Patients usually have a systemic response with tachycardia, and fever. This is the most common form of crisis.
- **Stroke.** The single most devastating consequence of sickle-cell disease is stroke. Stroke or silent stroke occurs in 10%–15% of children with sickle-cell disease. Children at risk of stroke can be identified by screening with transcranial Doppler ultrasound, with fast flow associated with increased stroke risk. These children may be offered strategies such as transfusion or treatment with hydroxyurea to reduce the risk of stroke.
- **Sickle chest syndrome.** This may follow a vaso-occlusive crisis and is the most common cause of death in adult sickle-cell disease. Bone marrow infarction results in fat embol to the lungs, which cause further sickling and infarction, leading to ventilatory failure if not treated.
- **Sequestration crisis.** Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children, the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction and adults may have no functional spleen. In adults, the liver may undergo sequestration with severe pain due to capillary stretching. Priapism may occur in affected individuals.
- **Aplastic crisis.** Infection of adult sicklers with human parvovirus B19 (erythrovirus) may result in a severe but self-limiting red cell aplasia. This results in profound anaemia, which may cause heart failure. Unlike in all other sickle crises, the reticulocyte count is low.
- **Pregnancy.** Pregnancy in sickle-cell disease requires planning and multidisciplinary management. Women with sickle-cell disease have increased pregnancy-related morbidity, which includes painful crisis, placental failure and thrombosis (Box 25.39).

**Investigations**

Patients with sickle-cell disease have a compensated anaemia, usually around 60–80 g/L. The blood film shows sickle cells, target cells and features of hyposplenism from a young age. A reticulocytosis is present. The presence of HbS can be demonstrated by exposing red cells to a reducing agent such as sodium dithionite; HbA gives a clear solution, whereas HbS polymerises to produce a turbid solution. This forms the basis of
emergency screening tests before surgery in appropriate ethnic groups, but cannot distinguish between sickle-cell trait and disease. The definitive diagnosis requires haemoglobin electrophoresis to demonstrate the absence of HbA. 2%–20% HbF and the predominance of HbS. Both parents of the affected individual will have sickle-cell trait.

Management

All patients with sickle-cell disease should receive prophylaxis with daily folic acid, and appropriate management of the hypersplenomegaly state that is uniformly found in these patients from an early age (see Box 25.37). Seasonal vaccination against influenza is also advised.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with fully genotyped blood wherever possible. Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications, such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesectioned and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disease and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxyethyladone has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises. The P-selectin inhibitor, crizanlizumab, is currently under review as an agent to reduce vasoocclusive crisis.

Relatively few allogeneic stem cell transplants from HLA-matched siblings have been performed, but this procedure appears to be potentially curative (p. 945).
Prognosis
In Africa, few children with sickle-cell anaemia survive to adult life without medical attention. Even with standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

Other abnormal haemoglobins
Haemoglobin C (HbC) disease, another beta-chain haemoglobinopathy, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one HbS gene and one HbC gene from their parents have haemoglobin SC disease, which behaves like a mild form of sickle-cell disease. SC disease is associated with a reduced frequency of crises, but is not uncommonly associated with complications in pregnancy and retinopathy.

Thalassaemias
Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesise a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point mutations causing no (α0) or reduced (α+) beta chain production.

Beta-thalassaemia
Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild microcytic anaemia and little or no clinical disability, which may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or, at best, produce very little; after the first 4–6 months of life, they develop profound transfusion-dependent hypochromic anaemia. The diagnostic features are summarised in Box 25.40. Intermediate grades of severity occur.

Management and prevention
See Box 25.41. Cure is now a possibility for selected children, with allogeneic HSCT (p. 945).

It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA analysis sufficiently early in pregnancy to allow termination. This examination is appropriate only if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

Alpha-thalassaemia
Reduced or absent alpha-chain synthesis is common in South-east Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.
- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

Some considerations specific to anaemia in old age are listed in Box 25.42.

Haematological malignancies
Haematological malignancies arise when the processes controlling proliferation or apoptosis are corrupted in blood cells because of acquired mutations in key regulatory genes. If mature differentiated cells are involved, the cells will have a low growth fraction and produce indolent
neoplasms, such as the low-grade lymphomas or chronic leukaemias, when patients have an expected survival of many years. In contrast, if more primitive stem or progenitor cells are involved, the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive, life-threatening illnesses such as the acute leukaemias or high-grade lymphomas. Involvement of pluripotent stem cells produces the most aggressive acute leukaemias. In general, haematological neoplasms are diseases of older patients, the exceptions being acute lymphoblastic leukaemia, which predominantly affects children, and Hodgkin lymphoma, which affects people aged 20–40 years. Management of young patients with haematological malignancy is particularly challenging (Box 25.43).

**Leukaemias**

Leukaemias are malignant disorders of the white cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days to weeks to many years, depending on the type.

**Terminology and classification**

Leukaemias are traditionally classified into four main groups:

- acute lymphoblastic leukaemia (ALL)
- acute myeloid leukaemia (AML)
- chronic lymphocytic leukaemia (CLL)
- chronic myeloid leukaemia (CML).

In acute leukaemia, there is proliferation of mutated haematopoietic stem and progenitor cells, with limited accompanying differentiation, leading to an accumulation of blasts, predominantly in the bone marrow, which causes bone marrow failure. In chronic leukaemia, the malignant clone is able to differentiate, resulting in an accumulation of more mature cells. Lymphoblastic and lymphoblastic cells are those derived from the lymphoid progenitor cells (B cells and T cells). Myeloid refers to the other lineages: that is, precursors of red cells, granulocytes, monocytes and platelets (see Fig. 25.2).

The diagnosis of leukaemia is usually suspected from an abnormal blood count, often including a raised white count, and is confirmed by examination of the bone marrow. This includes the morphology of the abnormal cells, analysis of cell surface markers (immunophenotyping), clone-specific chromosome abnormalities and molecular changes. These results are incorporated in the World Health Organization (WHO) classification of tumours of haematopoietic and lymphoid tissues; the subclassification of acute leukaemias is shown in Box 25.44. The features in the bone marrow not only provide an accurate diagnosis, but also give valuable prognostic information, increasingly allowing therapy to be tailored to the patient’s disease.

---

**25.43 Consequences of haematological malignancy in adolescence**

- **Tailored management protocols**: the most effective treatment schedules for leukaemia and lymphoma differ between children and adults. Adolescent patients may be most appropriately managed in specialist centres.
- **Psychosocial effects**: adolescents undergoing treatment for haematological malignancy may suffer significant consequences for their schooling and social development, and require support from a multidisciplinary team.
- **‘Late effects’**: adolescents who have been treated with chemotherapy and/or radiotherapy in childhood may be at risk of a wide range of complications, depending on the region irradiated, radiation dose and the drugs used. Particularly relevant complications in this age group include short stature, growth hormone deficiency, delayed puberty and cognitive dysfunction affecting schooling (after cranial irradiation). Long-term follow-up is often undertaken to detect and manage these late effects and to deal with consequences such as infertility and second malignancy.

---

**25.44 WHO classification of acute leukaemia**

- **Acute myeloid leukaemia (AML) with recurrent genetic abnormalities**
  - AML with t(8;21)(q22;q22.1), gene product RUNX1-RUNX1T1
  - AML with inv(16)(p13.1;q22), gene product CBFB-MYH11
  - Acute promyelocytic leukaemia (15;17), gene product PML-RARA
  - AML with t(9;11)(q21.3;q23.3), gene product MLLT3-KMT2A
  - AML with t(6;9)(p23;q34), gene product DEK-NUP214
  - AML with inv(3)(q21.3;q26.2) or t(3;3)(q21.3;q26.2), gene products GATA2, MECOM
  - AML (megakaryoblastic) with t(1;22)(p13.3;q13.3), gene product RBM15-MKL1
  - AML with mutated NPM1
  - AML with biallelic mutations of CEBPA

- **Acute myeloid leukaemia with myelodysplasia-related changes**
  - e.g. Following a myelodysplastic syndrome

- **Therapy-related myeloid neoplasms**
  - e.g. Alkylating agent or topoisomerase II inhibitor

- **Myeloid sarcoma**

- **Myeloid proliferations related to Down syndrome**

- **Acute myeloid leukaemia not otherwise specified**
  - e.g. AML with or without differentiation, acute myelomonocytic leukaemia, erythroleukaemia, megakaryoblastic leukaemia

- **Acute lymphoblastic leukaemia (ALL)**
  - B-lymphoblastic leukaemia/lymphoma
  - T-lymphoblastic leukaemia/lymphoma

---

**25.45 Risk factors for leukaemia**

**Ionising radiation**

- After atomic bombing of Japanese cities (myeloid leukaemia)
- Radiotherapy
- Diagnostic X-rays of the fetus in pregnancy

**Cytotoxic drugs**

- Especially alkylating agents and topoisomerase II inhibitors (therapy-related myeloid malignancies), usually after a latent period of several years with alkylating agents and a few months to 2 years with topoisomerase II inhibitors
- Industrial exposure to benzene

**Retroviruses**

- Adult T-cell leukaemia/lymphoma (ATLL) caused by human T-cell lymphotropic virus 1 (HTLV-1), most prevalent in Japan, the Caribbean and some areas of Central and South America and Africa

**Genetic**

- Identical twin of patients with leukaemia
- Down syndrome and certain other genetic disorders

**Immunological**

- Immune deficiency states (e.g. hypogammaglobulinaemia)

**Epidemiology and aetiology**

The incidence of leukaemia of all types in the population is approximately 10/10,000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 2.5:1 in acute leukaemia, 2.1:1 in chronic lymphocytic leukaemia and 1.3:1 in chronic myeloid leukaemia. Geographical variation in incidence does occur, the most striking being the rarity of chronic lymphocytic leukaemia in Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak of incidence in children aged 1–5 years. All forms of acute myeloid leukaemia have their lowest incidence in children and young adult life and there is a striking rise over the age of 50. Chronic leukaemias occur mainly in middle and old age.

The cause of the leukaemia is unknown in the majority of patients. Several risk factors have been identified (Box 25.45).
Acute leukaemia

Mutations in haematopoietic stem cells produce leukemic stem cells. Proliferation of these cells that do not mature leads to an accumulation of primitive cells that take up more and more marrow space at the expense of the normal haematopoietic cells. Eventually, this proliferation spills into the blood. Acute myeloid leukaemia (AML) is about four times more common than acute lymphoblastic leukaemia (ALL) in adults. In children, the proportions are reversed, the lymphoblastic variety being more common. The clinical features are usually those of bone marrow failure (anaemia, bleeding or infection; pp. 932, 937 and 939).

Investigations

Blood examination usually shows anaemia with a normal or raised MCV. The leucocyte count may vary from as low as 1 x 10⁹/L to as high as 500 x 10⁹/L or more. In the majority of patients, the count is below 100 x 10⁹/L. Severe thrombocytopenia is usual but not invariable. Frequently, blast cells are seen in the blood film, but sometimes the blast cells may be infrequent or absent. A bone marrow examination will confirm the diagnosis. The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells in varying degrees (but more than 20% of the cells) (Fig. 25.25). The presence of Auer rods in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia. Classification and prognosis are determined by immunophenotyping and chromosome and molecular analysis, as shown in Fig. 25.26.

Management

Ideally, whenever possible, patients with acute leukaemia should be treated within a clinical trial. If a decision to embark on specific therapy has been taken, the patient should be prepared as recommended in Box 25.46. It is unwise to attempt aggressive management of acute leukaemia unless adequate supportive therapy can be provided.

The aim of treatment is to destroy the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of the haematopoietic tissues will occur. The detail of the schedules for treatments can be found in specialist texts. The drugs most commonly employed are listed in Box 25.47. Generally, if a patient fails to go into remission with induction treatment, alternative drug combinations may be tried, but the outlook is poor unless remission can be achieved. Disease that relapses during treatment or soon after the end of treatment, including after HSCT, carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective. In some patients, alternative palliative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation. Drugs used for this purpose include hydroxycarbamide and mercaptopurine. The aim is to reduce the blast count without inducing bone marrow failure.

Specific therapy

Acute myeloid leukaemia (AML) AML is predominantly a disease of those in old age and many patients are frail. Treatment has become more complex in the recent years and is increasingly tailor-made for AML subgroups defined by genetic abnormalities or persistence of measurable residual disease (MRD). The first decision must be whether or not to give specific treatment to attempt to achieve remission. The most effective remission induction therapy is based around intensive combination chemotherapy. This is generally aggressive, has numerous side-effects and may not be appropriate for the very old or patients with serious comorbidities. In these patients, supportive treatment can effect considerable improvement in well-being, but there remains considerable unmet need. Low-intensity chemotherapy, such as low-dose cytosine arabinoside or azacitidine, is frequently used in older and frailer patients, but this induces remission in less than 20% of patients. Recently, the addition of the BCL-2 inhibitor venetoclax to cytosine and azacitidine has shown improved overall survival, especially the combination with azacitidine (Fig. 25.27).

Remission induction. In this phase, a fraction of the tumour is killed by combinations of chemotherapy drugs. The standard of care for remission induction in AML is daunorubicin with cytosine arabinoside given for 7–10 days in two cycles. Patients with a good or standard risk karyotype, including normal karyotype, benefit from the addition of the antibody-drug conjugate gemtuzumab ozogamicin which targets CD33 on the AML cell and delivers the DNA damaging drug calicheamicin directly into the cell (see Fig. 25.27), while AML with the FLT3-ITD mutation benefits from the addition of the

25.46 Preparation for specific therapy in acute leukaemia

- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Screen for COVID-19
- Anaemia corrected by red cell concentrate transfusion
- Thrombocytopenic bleeding controlled by platelet transfusions
- If possible, central venous catheter (e.g. Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy, fluids, blood products and other supportive drugs
- Tumour lysis risk assessed and prevention started: fluids with allopurinol or rasburicase
- Therapeutic regimen carefully explained to the patient and informed consent obtained
- Consideration of entry into clinical trial

FL33 inhibitor midostaurin (see Fig. 25.27). The patient goes through a period of severe bone marrow hypoplasia lasting 3–4 weeks and requires intensive support and inpatient care from a specially trained multidisciplinary team. The aim is to achieve remission, a state in which the blood counts return to normal and the marrow blast count is less than 5%. Quality of life is highly dependent on achieving remission, hence remission induction is the preferred therapy for all patients who are considered fit enough to undergo such treatment.

- Remission consolidation. If remission has been achieved, residual disease is attacked by therapy during the consolidation phase. This consists of a number of courses of chemotherapy, most commonly 1–2 courses of high-dose cytosine arabinoside, again resulting in periods of marrow hypoplasia. In poor-prognosis AML, defined by poor risk cytogenetic/molecular genetic abnormalities or persistent MRD, this may include allogeneic HSCT.
- Remission maintenance. Maintenance therapy has only recently become an effective tool for some patients with AML compared to its long-established role in ALL. Patients not undergoing allogeneic HSCT with FL33 mutated AML receive one year of maintenance with midostaurin and other patients may benefit from azacitidine.

Acute promyelocytic leukaemia (APML) A subtype of AML, called acute promyelocytic leukaemia (APML), is characterised by a block in differentiation of malignant promyelocytes. These cells accumulate and lead to bone marrow failure and a tendency to severe bleeding, including into the CNS, because of enhanced fibrinolysis and DIC induced by the procoagulant proteins in the malignant cells, e.g. tPA and uPA. This leukaemia is caused by a translocation of genes on chromosomes 15 (PML) and 17 (RARA) producing the PML-RARA rearrangement which drives the leukaemia. APML carries the best prognosis of all AML if the patient survives the initial bleeding risk. Furthermore, low risk cases can be treated with a non-chemotherapy regimen of differentiation therapy with all-trans-retinoic acid (ATRA) and arsenic trioxide (ATO). Higher-risk patients are treated with ATRA and anthracycline-based chemotherapy. The prognosis is excellent with 90% cure rate for patients receiving treatment. However, the early death rate from bleeding remains problematic and intensive supportive care and immediate introduction of ATRA therapy is vital to prevent this.

Acute lymphoblastic leukaemia (ALL) This is predominantly a disease of childhood with a mean age of 2–4 years. However, it also occurs in adulthood where it is more difficult to treat and carries a poorer prognosis. Once again there are three phases of therapy with treatment tailor-made to risk groups based on genetic abnormalities and levels of MRD:

- Remission induction – As with AML the aim is to achieve remission using a combination of chemotherapy drugs given over a 4-week period. The drugs commonly used are dexamethasone, vincristine, anthracyclines, methotrexate, mercaptopurine and asparaginase. Induction therapy in ALL is often less damaging and better tolerated than AML, however, the high dosage of steroids coupled with neutropenia carries a high risk of infections, including fungal
Supportive therapy
Aggressive and potentially curative therapy, which involves periods of severe bone marrow failure, would not be possible without appropriate supportive care. The following problems commonly arise.

Anaemia Anaemia is treated with red cell concentrate transfusions.

Bleeding Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Recent trials have confirmed that in acute leukaemia prophylactic platelet transfusion should be given to maintain the platelet count above 10 x 10^9/L. Coagulation abnormalities occur and need accurate diagnosis and treatment, especially in APML (see above).

Infection So-called neutropenic sepsis is a major complication of acute leukaemia and its treatment. Every leukaemia centre will have a written definition and management policy for this common event. UK NICE guidelines define neutropenic sepsis as fever (>38°C) lasting over 1 hour in a neutropenic patient (neutrophils <0.5 x 10^9/L) or with other signs or symptoms of significant sepsis (see also p. 198). Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given according to the perceived severity of the sepsis illness and local bacteriological resistance patterns. Increasingly, low-risk cases of neutropenic sepsis are treated with single antibiotics, e.g. piperacillin/tazobactam. Higher-risk cases are managed with regimens such as a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam) or a single-agent beta-lactam (e.g. meropenem). The organisms most commonly associated with severe neutropenic sepsis are Gram-positive bacteria, such as Staphylococcus aureus and Staphylococcus epidermidis, which are present on the skin and gain entry via cutaneous and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as Escherichia coli, Pseudomonas and Klebsiella spp. are likely to cause rapid clinical deterioration and must be covered with initial empirical antibiotic therapy. Gram-positive infection may require vancomycin or teicoplanin therapy. If fever has not resolved after 3–5 days and there is evidence for a disseminated fungal infection on CT scans or sensitive blood tests, empirical antifungal therapy (e.g. a liposomal amphotericin B preparation, voriconazole or caspofungin) is added.

Patients with ALL are susceptible to infection with Pneumocystis jirovecii (Ch. 14), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis may require either induced sputum, bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal Candida infection is common. Fluconazole is effective for the treatment of established local infection and for prophylaxis against systemic candidaemia. Prophylaxis against other systemic fungal infections including Aspergillus, for example itraconazole or posaconazole, is usual practice during high-risk intensive chemotherapy. This is often used along with sensitive markers of early fungal infection to guide treatment initiation (a ‘pre-emptive approach’).

For systemic fungal infection with Candida or aspergillus, intravenous liposomal amphotericin, caspofungin or voriconazole is required for up to 3 weeks. In systemic Candida infection intravenous catheters should be removed.

Reactivation of herpes simplex infection (Ch. 13) occurs frequently around the lips and nose during ablative therapy for acute leukaemia, and is treated with aciclovir. This may also be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chickenpox or, after reactivation, as shingles (Ch. 13) should be treated in the early stage with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable but may contribute to staff awareness of careful reverse barrier nursing practice. The isolation can be psychologically stressful for the patient.
Metabolic problems Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic and diarrhoea is common as a consequence of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy (tumour lysis syndrome; p. 142) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may lead to renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome, e.g. acute leukaemia with a white cell count of more than 100 × 10^9/L, prophylactic rasburicase (a recombinant urate oxidase enzyme) is used. Occasionally, dialysis may be required.

Psychological problems Psychological support is a key aspect of care. Patients should be kept informed, and their questions answered and fears allayed as far as possible. A multidisciplinary approach to patient care involves input from many services, including psychology. Key members of the team include haematology specialist nurses, who are often the central point of contact for patients and families throughout the illness.

Haematopoietic stem cell transplantation (HSCT) This is described on page 945. In patients with high-risk acute leukaemia, allogeneic HSCT can improve 5-year survival from 20% to around 50%. Reduced-intensity conditioning has allowed HSCT to be delivered to a higher proportion of patients with acute leukaemias, up to the age of about 65 years. Improved knowledge of the biology of leukaemia alters the definition of high risk. For example, patients with AML with a normal karyotype and isolated NPM1 gene mutations are considered good risk and are not routinely transplanted in first remission. However, otherwise similar patients with isolated FIP1L1-PDGF mutations are poor risk and considered for transplant in first remission.

Prognosis Without treatment, the median survival of patients with acute leukaemia is about 5 weeks. This may be extended to a number of months with supportive treatment. Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 25.48 shows the survival in ALL and AML and the influence of prognostic features. The level of detectable leukaemia cells after induction therapy, called measurable residual disease (MRD), can be a powerful prognostic tool and is now used routinely in some forms of acute leukaemia (e.g. ALL and AML with NPM1 mutation) to determine subsequent consolidation therapy.

Advances in treatment have led to steady improvement in survival from acute leukaemia. Some 90% of children with ALL are cured and about 50% of adults aged less than 60 years are cured from AML. As discussed above, APLM has a 90% cure rate. Prognosis remains poor in most other groups of patients with acute leukaemias, especially in old age. Current trials aim to improve survival, especially in standard and poor-risk disease, with strategies that include better use of allogeneic HSCT, better ability to predict relapse using MRD and new targeted therapies (see Figs. 25.27 and 25.28).

Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is a myeloproliferative stem cell disorder resulting in proliferation of all haematopoietic lineages, but manifesting predominantly in the granulocytic series. Maturation of cells proceeds fairly normally. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years. It is rare, with an annual incidence in the UK of 1.8/100,000, and accounts for 15% of all leukaemias. It is found in all races.

The defining characteristic of CML is the chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the breakpoint cluster region (BCR). The fragment from chromosome 9 that joins the BCR carries the abl oncogene, which forms a fusion gene with the remains of the BCR. This BCR-ABL fusion gene codes for a 210kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene (p. 132), influencing cellular proliferation, differentiation and survival and is a target for very effective tyrosine kinase inhibitor (TKI) therapy (Fig. 25.29 and see Box 25.21). In some patients in whom conventional chromosomal analysis does not detect a Ph chromosome, the BCR-ABL gene product is detectable by molecular techniques.

Natural history

The disease has three phases:

- A chronic phase, in which the disease is responsive to treatment and is easily controlled, which used to last 3–5 years. With the introduction of the tyrosine kinase inhibitors (TKI) (Box 25.49), this phase has been prolonged to encompass a normal life expectancy in many patients.
- An accelerated phase (not always seen), in which disease control becomes more difficult.
- Blast crisis, in which the disease transforms into an acute leukaemia, either myeloblastic (70%) or lymphoblastic (30%), which is relatively refractory to treatment. This is the cause of death in the majority of patients; survival is therefore dictated by the timing of blast crisis, which cannot be predicted. Prior to TKI therapy (see below), approximately 10% of patients per year would transform; the transformation rate has been reduced to 0.5%–2.5% per year with TKI therapy.

Clinical features

Symptoms at presentation may include lethargy, weight loss, abdominal discomfort, gout and sweating, but about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10% the enlargement is massive, extending to over 15 cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual.

Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to 600 × 10^9/L. In about one-third of patients, there is a very high platelet
and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cells increases. Blast transformation is characterised by a dramatic increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophilia tends to increase as the disease progresses.

Bone marrow should be obtained to confirm the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, and RNA analysis to demonstrate the presence of the BCR-ABL gene product. Blood LDH is elevated and uric acid may be high due to increased cell breakdown.

Management

Chronic phase

There are now five available tyrosine kinase inhibitors (TKIs) for the treatment of CML (see Box 25.49). These specifically inhibit BCR-ABL tyrosine kinase activity. Imatinib, nilotinib and dasatinib are recommended as first-line therapy in chronic phase CML; they usually normalise the blood count within a month and within 3–6 months produce complete cytogenetic response (disappearance of the Ph chromosome) in some 90% of patients. Patients are monitored by 3-monthly real-time quantitative polymerase chain reaction (qPCR) for BCR-ABL mRNA transcripts in blood. The aim is to reduce the BCR-ABL transcript levels by 3–5 logs from baseline and this is called major molecular response (MMR). A proportion of patients achieve a complete molecular response where the transcripts are not detectable by PCR. Up to 50% of patients with a complete or major molecular response may be able to discontinue TKI therapy. For those failing to respond or who lose their response and progress on first-line therapy, options include switching to a different TKI (see Box 25.49). Some patients develop detectable mutations in the BCR-ABL gene, which causes resistance to one or more of the TKIs. The T315I mutation is particularly problematic as this causes wide-ranging resistance, but the third-generation TKI ponatinib can be effective. Allogeneic HSCT (p. 945) is now reserved for patients who fail TKI therapy. Hydroxyurea and interferon were previously used for control of disease. Hydroxyurea is still useful in palliative situations and interferon is used in women planning pregnancy.

Accelerated phase and blast crisis

Management is more difficult. For patients in accelerated phase, TKI therapy is indicated, most commonly with nilotinib or dasatinib. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 25.49) is better if disease is lymphoblastic rather than myeloblastic. Second- or third-generation TKIs such as dasatinib are used in combination with chemotherapy to try to achieve remission. In younger and fitter patients
an allogeneic HSCT is appropriate therapy if a return to chronic phase is achieved. Hydroxycarbamide can be an effective single agent and low-dose cytarabine can also be used palliatively in older patients.

### Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common variety of leukaemia, accounting for 30% of cases. The male-to-female ratio is 2:1 and the median age at presentation is 65–70 years. CLL is characterised by the clonal expansion of small mature-looking B-cells. Failure to apoptose because of overexpression of BCL-2 and in some cases mutations in TP53 leads to an ever-increasing accumulation of immuno-incompetent leukaemic B cells. This is to the detriment of immune function and normal bone marrow haematopoiesis. CLL cells are dependent on abnormal and persistent signalling through the B-cell receptor (BCR) pathway. Drugs that can inhibit these pathways are now available and show great promise (Fig. 25.30).

#### Clinical features

The onset is usually insidious. Indeed, in around 70% of patients the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss; these more often occur later in the course of the disease or in disease that is advanced at presentation.

#### Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis (>5 × 10^9/L) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B-cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T-cell antigen CD5. On flow cytometry, some people are shown to have circulating CLL cells at a level less than 5 × 10^9/L. This is known as monoclonal B lymphocytosis of uncertain significance (MBL). Such patients progress to CLL at a rate of 1% per year.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test, as autoimmun anaemia may occur (p. 958). Serum immunoglobulin levels should be estimated to establish the degree of hypogammaglobulinaemia, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for progression (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. The main prognostic factor is stage of disease (Box 25.50); however, loss of chromosome 17p or mutation in the TP53 gene, which resides at this genetic locus, is a powerful prognostic maker of poor outcome and predictor of response to therapy. A mutation in TP53 is present in <10% of patients at presentation, but rises to 30% of cases at relapse. This test should be performed in all patients prior to the initiation of therapy.

#### Management

No specific treatment is required for most clinical stage A patients, unless progression occurs. The patient should be offered clear information about CLL and be reassured about the indolent nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety.

Treatment is required only if there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count, autoimmune haemolytic anaemia or thrombocytopenia. Initial therapy for those requiring treatment (progressive stage A and stages B and C) is based on the age and fitness of the patient and the TP53 mutation status. For patients who are under 70 years, fit and TP53 mutation-negative, fludarabine in combination with the alkylating agent cyclophosphamide and the anti-CD20 monoclonal antibody rituximab (FGR) is standard care. For older, less fit patients, rituximab is combined with gentler chemotherapy: bendamustine or oral chlorambucil. A more potent anti-CD20 antibody, obinutuzumab, produces better responses in combination with chlorambucil than rituximab.

Ibrutinib inhibits Bruton’s tyrosine kinase and idelalisib inhibits PI3 kinase, both components of the BCR pathway (see Fig. 25.30). Ibrutinib and idelalisib are licensed for relapsed CLL, but are effective in TP53-mutated disease at all stages. Ibrutinib is first-line standard of care in TP53-mutated CLL. CLL cells are resistant to apoptosis and express increased levels of anti-apoptotic proteins, including BCL-2. Venetoclax is an inhibitor of BCL-2 and is so effective at killing CLL cells that it frequently causes tumour lysis syndrome when first administered. Venetoclax is licensed in combination with obinutuzumab for the treatment of adult patients with previously untreated CLL and is attractive as it is given for a fixed period of two years. Venetoclax can also be used for patients with TP53 mutation or who have failed previous therapy. Bone marrow failure or autoimmune cytopenias may respond to glucocorticoid treatment or rituximab.

Supportive care is increasingly required in progressive disease, such as transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections and, for some patients with...
hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymphadenopathy that is causing discomfort or local obstruction and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism and can relieve massive splenomegaly.

**Prognosis**

The majority of clinical stage A patients have a normal life expectancy, but patients with advanced CLL are more likely to die from their disease or infectious complications. Survival is influenced by other prognostic features of the leukaemia, particularly TP53 mutation status, and traditionally whether patients can tolerate and respond to fludarabine-based treatment. In those able to be treated with chemotherapy and rituximab, 90% are alive 4 years later. The newer agents may replace and surpass immunochemotherapy as first-line therapy. As in other haematological malignancies the presence of MRD is prognostically important. Ibrutinib and especially venetoclax are more likely to produce an MRD negative state. Rarely, CLL transforms to an aggressive high-grade lymphoma, called Richter's transformation.

**Prolymphocytic leukaemia**

Prolymphocytic leukaemia (PLL) is a form of chronic leukaemia found mainly in males over the age of 60 years; 25% of cases are of T cell origin. There is typically massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often in excess of 400 × 10⁹/L. Effusions and involvement of skin are well recognized. The characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis very poor. Leukapheresis, splenectomy and chemotherapy may be tried. The anti-CD52 antibody alemtuzumab, when given intravenously, has produced responses in some 90% of patients with T-PLL. Younger patients who respond to treatment may be considered for allogeneic HSCT.

**Hairy cell leukaemia**

This is a rare chronic B-cell lymphoproliferative disorder. The male-to-female ratio is 6:1 and the median age at diagnosis is 50 years. Presenting symptoms are general ill health and recurrent infections. Splenomegaly occurs in 90% but lymph node enlargement is unusual. Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B-lymphocyte immunotype, but they also characteristically express CD25 and CD103. Recently, all patients with hairy cell leukaemia have been found to have a mutation in the BRAF gene and this may become a therapeutic target. Chemotherapy treatments such as cladribine and deoxycoformycin can produce long-lasting remissions.

**Myelodysplastic syndromes**

Myelodysplastic syndromes (MDSs) constitute a group of clonal haematopoietic disorders with the common features of ineffective blood cell production and a tendency to progress to AML. As such, they are pre-leukaemic and represent genetic steps in the development of leukaemia. These genetic abnormalities have been identified and are increasingly present with age as a manifestation of clonal haematopoiesis, occurring in about 20% of patients over the age of 80. Blood counts are normal (clonal haematopoiesis of indeterminate potential, CHIP), but there is an increased risk of developing MDS, AML or non-haematological disease such as coronary artery disease. The common CHIP gene mutations include DNMT3a, TET2 and ASXL1.

Some 80% of patients with MDS have one or more acquired mutations in specific genes and these are now routinely identified by multi-gene next generation sequencing (NGS) using a so-called “myeloid gene panel”. Some are associated with specific phenotypes of MDS, e.g. 80% of cases with ring sideroblasts have a mutation in the splice factor gene SF3B1. Others have prognostic significance, e.g. TP53 or two or more mutations carry a poor prognosis. Chromosome analysis frequently reveals abnormalities, particularly of chromosome 5 or 7.

MDS presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), usually in older people (median age at diagnosis is 73 years). The overall incidence is 4/100,000 in the population, rising to more than 30/100,000 in the over-seventies. The blood film is characterised by cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular, with dysplastic changes in at least 10% of cells of one or more cell lines. Blast cells may be increased but do not reach the 20% level that indicates acute leukaemia. The WHO classification of MDS is shown in Box 25.51.

**Prognosis**

The natural history of MDS is progressive worsening of dysplasia leading to fatal bone marrow failure or progression to AML in 30% of cases. The time to progression varies (from months to years) with the subtype of MDS, being slowest in MDS with ring sideroblasts and single-lineage dysplasia and most rapid in MDS with excess blasts. The revised International Prognostic Scoring System (IPSS-R) predicts clinical outcome based on karyotype and cytopenias in blood, as well as percentage of bone marrow blasts (Box 25.52). There are five prognostic groups. The median survival for low-risk patients (IPSS-R very low and low) is 5–9 years, that for the intermediate group is 3 years and that for high-risk patients (IPSS-R high and very high) is 1–1.5 years.

**Management**

For the vast majority of patients who are in old age, the disease is incurable, and supportive care with red cell and platelet transfusions is the mainstay of treatment. A trial of erythropoiesis stimulating agents (ESA) is recommended in some patients with low-risk MDS (IPSS-R very low, low and intermediate) to improve haemoglobin. Responders have better quality of life, lower risk of progression to AML and possibly better overall survival. Granulocyte colony stimulating factor (G-CSF) is recommended for short-term use in neutropenic patients with active infection. A rare subtype called MDS with isolated del(5q) responds well to the immunomodulatory drug lenalidomide, with two-thirds of anaemic patients becoming transfusion-independent for up to 2 years. Allogeneic stem cell transplantation may afford a cure in patients with a good performance status and is considered in high-risk patients (IPSS-R high and very high) and some low-risk patients. The hypomethylating agent azacitidine has improved survival by a median of 9 months compared to supportive care or low intensity chemotherapy for high-risk patients, and is a recommended standard of care for those not eligible for transplantation.

*The IPSS-R is based on three prognostic factors: the blast percentage in bone marrow; karyotype; and number and degree of blood cytopenias. A score is derived from which patients can be stratified into five risk categories for survival and leukaemic transformation.

---

*Fig. 25.31* Schema of lymph node architecture. Different lymphocyte populations reside in different areas of the node: B cells in the follicles, T cells in the paracortex and plasma cells in the medulla. B cells are selected for antigen in the follicle centre. Errors during this process result in B-cell lymphomas, which are by far the most common type.

### Lymphomas

These neoplasms arise from lymphoid tissues and are diagnosed from the pathological findings on biopsy as Hodgkin or non-Hodgkin lymphoma. The majority are of B-cell origin. Non-Hodgkin lymphomas are classified as low- or high-grade tumours on the basis of their proliferation rate. The normal architecture of the lymph node is outlined in *Fig. 25.31*,

- **High-grade tumours** divide rapidly, are typically present for a matter of weeks before diagnosis, and may be life-threatening with high risk of extranodal involvement.
- **Low-grade tumours** divide slowly, may be present for many months before diagnosis, and typically behave in an indolent fashion.

#### Hodgkin lymphoma

The histological hallmark of Hodgkin lymphoma (HL) is the presence of Reed–Sternberg cells: large, malignant lymphoid cells of B-cell origin (*Fig. 25.32*). They are often present only in small numbers, but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and granulocytes, including eosinophils.

The epidemiology of HL is shown in *Box 25.53* and its histological WHO classification in *Box 25.54*.

---

*Fig. 25.32* Hodgkin lymphoma. In the centre of this lymph node biopsy is a large typical Reed–Sternberg cell with two nuclei containing a prominent eosinophilic nucleolus.

### 25.53 Epidemiology and aetiology of Hodgkin lymphoma

- **Incidence**
  - Approximately 4 new cases/100,000 population/year

- **Sex ratio**
  - Slight male excess (1.5:1)

- **Age**
  - Median age 31 years; first peak at 20–35 years and second at 50–70 years

- **Aetiology**
  - Unknown
  - More common in patients from well-educated backgrounds and small families
  - Three times more likely with a past history of infectious mononucleosis but no definitive causal link to Epstein–Barr virus infection proven

### 25.54 WHO pathological classification of Hodgkin lymphoma (HL)

<table>
<thead>
<tr>
<th>Type</th>
<th>Histology classification</th>
<th>Proportion of HL</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nodular lymphocyte-predominant HL</td>
<td>Nodular sclerosing</td>
<td>5%</td>

<tr>
<td>Classical HL</td>
<td>Mixed cellularity</td>
<td>20%</td>
</tr>
<tr>
<td></td>
<td>Lymphocyte-rich</td>
<td>5%</td>
</tr>
<tr>
<td></td>
<td>Lymphocyte-depleted</td>
<td>Rare</td>
</tr>
</tbody>
</table>

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. It has biological features, such as CD20-positive Hodgkin cells, and clinical features that make it more akin to a low-grade B-cell non-Hodgkin lymphoma. Classical HL is divided into four histological subtypes from the appearance of the Reed–Sternberg cells and surrounding reactive cells. The nodular sclerosing type is more common in young patients and in women. Mixed cellularity is more common in older patients. Lymphocyte-rich HL usually presents in men. Lymphocyte-depleted HL is rare and probably represents large-cell or anaplastic non-Hodgkin lymphoma.

#### Clinical features

There is painless, rubbery lymphadenopathy, usually in the neck or supravclavicular fossae; the lymph nodes may fluctuate in size. Young patients with nodular sclerosing disease may have large mediastinal masses that are surprisingly asymptomatic, but may cause dry cough and some
breathlessness. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present, but does not always indicate disease in those organs. Spread is contiguous from one node to the next, and extranodal disease, such as bone, brain or skin involvement, is rare. Systemic symptoms include so-called ‘B symptoms’ of drenching night sweats, fever and loss of 10% body weight. Other symptoms can include pruritis and rarely, but dramatically, alcohol-induced pain within lymph nodes.

**Investigations**

Treatment of HL depends on the stage at presentation; investigations therefore aim not only to diagnose lymphoma, but also to determine the extent of disease (Box 25.55).

- **FBC** may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor, particularly in advanced disease. An eosinophilia, neutrophilia or thrombocytosis may be present.
- **ESR** may be raised and is an adverse prognostic factor.
- **Renal function tests** are required to ensure function is normal prior to treatment.
- **Liver function** may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatitis.
- **LDH** may be raised and is an adverse prognostic factor.
- **Chest X-ray** may show a mediastinal mass.
- **CT scan** of chest, abdomen and pelvis permits staging. Bulky disease (>10 cm in a single node mass) is an adverse prognostic feature.
- **Positron emission tomography-CT (PET-CT)** scanning identifies nodes involved with HL that are ¹⁸fluorodeoxyglucose (FDG)-avid and this allows more accurate staging and monitoring of response (Fig. 25.33).
- **Lymph node biopsy** may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 25.34).

**Management**

Given the high cure rate and excellent prognosis of a majority of young and middle-aged patients with HL, the aim is to maximize cure rates while minimising long-term treatment-related toxicity. Treatment approaches involve defining patients as early-stage disease (stages IA and IIA) or advanced stage disease (IB, IIB, III and IV). The ABVD regimen (doxorubicin (adriamycin), bleomycin, vinblastine and dacarbazine) is widely used in the UK, while the more intensive BEACOPP regimen (bleomycin, etoposide, doxorubicin (adriamycin), cyclophosphamide, vincristine (oncovin), procarbazine, prednisolone) is a more effective alternative, though with a greater risk of side-effects including infertility and treatment-related MDS and AML.

Standard therapy for early-stage patients without additional risk factors, such as bulk disease or high ESR, is two cycles of ABVD combined with 20Gy radiotherapy to the involved sites of disease. Standard therapy for early-stage patients with additional risk factors is four cycles of ABVD combined with 30Gy radiotherapy. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues and new planning techniques continue to improve targeting of radiotherapy. Nevertheless, the long-term risks of second cancers and heart and lung disease within the radiation fields remain a concern, especially for young people with a high cure rate and potentially decades of life ahead of them. Early-stage patients who have a negative FDG PET-CT scan after...
three or four cycles of combination chemotherapy can safely omit radiotherapy. Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a breast screening programme. Patients continuing to smoke after lung irradiation are at particular risk of future lung cancer.

ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. The incidence of infertility and secondary myelodysplasia/AML is low with this regimen but higher with BEACOPP.

Patients with advanced-stage disease are most commonly managed with chemotherapy alone. Standard treatment in the UK is 6–8 cycles of ABVD, followed by an assessment of response. A negative FDG PET-CT after two cycles of ABVD (interim PET-2 response) predicts a very good outcome from continuing with up to six cycles of ABVD. Indeed, the same outcome can be achieved by omitting the bleomycin from the last four cycles and using just AVD, thus reducing the risk of lung toxicity. Even more impressive results of >90% 5-year progression-free survival can be achieved with just four cycles of BEACOPP if the interim PET-2 scan is negative. Patients who have a positive FDG PET-CT after two cycles, however, have a very high relapse risk if they continue with ABVD, with only 13% being relapse-free at 2 years. Switching to BEACOPP from ABVD or continuing with BEACOPP for six cycles in these patients improves the relapse-free survival to approximately 65–90%.

Patients with relapsed disease that responds to salvage chemotherapy and ideally becomes FDG PET-CT-negative should be considered for autologous stem cell transplantation (p. 945). Those with resistant disease might benefit from an allogeneic stem cell transplant. Brentuximab vedotin is an antibody–drug conjugate directed against CD30 on the Reed–Sternberg cell surface. This antibody delivers the antimitotic toxin monomethyl auristatin E to the Hodgkin cells and, as a single agent, can produce good responses in patients who have failed, or are not suitable for, an autologous transplant and can be a “bridge” to an allogeneic transplant. Reed–Sternberg cells over-express the cell surface protein Programme Death Ligand 1 (PD-L1). This engages with Programme Death Protein 1 (PD-1) on T cells and leads to T-cell ‘exhaustion’ (see Fig. 7.12). This ‘immune checkpoint’ is an important programmed survival mechanism for Reed–Sterberg cells. The immunotherapy drugs pembrolizumab and nivolumab can inhibit this ‘checkpoint’ in the immune response and allow T-cell killing of Reed–Sterberg cells. Both drugs are available for patients who have failed multiple lines of treatment and can produce further remissions.

**Prognosis**

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy, followed by involved field radiotherapy, and the great majority are cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group. Omitting radiotherapy in the majority of FDG PET-CT-negative patients is one major step forward in this regard.

Historically, between 50% and 70% of those with advanced-stage HL were cured. The Hasenclever index (Box 25.56) can be helpful in assigning approximate chances of cure when discussing treatment plans with patients. More recent data using FDG PET-CT to direct therapy suggests that long-term survival is improving to beyond 80%. Patients who fail to respond to initial chemotherapy or relapse within a year of initial therapy have a poor prognosis, but some may achieve long-term survival after autologous HSCT. Patients relapsing after 1 year may obtain long-term survival with further chemotherapy alone, but fit patients frequently proceed to autologous HSCT.

### Non-Hodgkin lymphoma

Non-Hodgkin lymphoma (NHL) represents a monoclonal proliferation of lymphoid cells of B-cell (90%) or T-cell (10%) origin. The incidence of these tumours increases with age, to 62.8 million population per annum at age 75 years, and the overall rate is increasing at about 3% per year.

The epidemiology of NHL is shown in Box 25.57. Previous classifications were based principally on histological appearances. The current WHO classification stratifies according to cell lineage (T or B cells) and incorporates clinical features, histology, genetic abnormalities and concepts related to the biology of the lymphoma. Clinically, the most important factor is grade, which is a reflection of proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months or even years before presentation, runs an indolent course, but is frequently disseminated at diagnosis and not curable by conventional therapy. Of all cases of NHL in the developed world, over 50% are either diffuse large B-cell NHL (high-grade) or follicular NHL (low-grade) (Fig. 25.35). Other forms of NHL, including Burkitt lymphoma, mantle cell lymphoma, mucosa-associated lymphoid tissue (MALT) lymphomas and T-cell lymphomas, are individually less common.

#### Clinical features

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement (Fig. 25.36), which may be associated with systemic upset: weight loss, sweats, fever and itching. Hepatosplenomegaly may be present. Sites of extranodal involvement include the bone marrow, gut, thyroid, lung, skin, tests, brain and, more rarely, bone. Bone marrow involvement is more common in low-grade (50%–60%) than high-grade

25.57 Epidemiology and aetiology of non-Hodgkin lymphoma

Incidence
- 12 new cases/100,000 people/year

Sex ratio
- Slight male excess

Age
- Median age 65–70 years

Aetiology
- No single causative abnormality described
- Lymphoma is a late manifestation of HIV infection (Ch. 14)
- Specific lymphoma types are associated with viruses: e.g. Epstein–Barr virus (EBV) with post-transplant NHL, human herpesvirus 8 (HHV8) with a primary effusion lymphoma, and human T-cell lymphotropic virus (HTLV-1) with adult T-cell leukaemia lymphoma
- Gastric lymphoma can be associated with Helicobacter pylori infection
- Some lymphomas are associated with specific chromosomal translocations:
  - The t(14;18) in follicular lymphoma results in the dysregulated expression of the BCL-2 gene product, which inhibits apoptotic cell death
  - The t(8;14) found in Burkitt lymphoma and the t(11;14) in mantle cell lymphoma alter function of c-myc and cyclin D1, respectively, resulting in malignant proliferation
  - Large B-cell lymphomas with rearrangements of c-myc with BCL-2 and/or BCL-6 (double and triple hit lymphomas)
- Lymphoma occurs in congenital immunodeficiency states and in immunosuppressed patients after organ transplantation

Fig. 25.35 Histology of non-Hodgkin lymphoma. A (Low-grade) follicular or nodular pattern. B (High-grade) diffuse pattern.

Fig. 25.36 Bulky axillary lymphadenopathy with distended superficial veins in a patient presenting with high-grade lymphoma. From Howard MR, Hamilton PJ. Haematology: An illustrated colour text, 4th edn. Edinburgh: Elsevier Ltd; 2013.

Investigations

These are as for HL, but in addition the following should be performed:
- Bone marrow aspiration and trephine to identify bone marrow involvement.
- Immunophenotyping of surface antigens to distinguish T-cell from B-cell tumours. This may be done on blood, marrow or nodal material.
- Cytogenetic analysis to detect chromosomal translocations, particularly rearrangements of the oncogene c-MYC and molecular testing for T-cell receptor or immunoglobulin gene rearrangements.
- Immunoglobulin determination. Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- Measurement of urate levels. Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started as a consequence of tumour lysis syndrome.
- HIV testing. HIV is a risk factor for some lymphomas and affects treatment decisions.
- Hepatitis B and C testing. This should be done prior to therapy with rituximab.

Management

Low-grade NHL

The majority of patients (80%) present with advanced stage disease and will run a relapsing and remitting course over several years. Overall survival has improved in recent years with more treatment options. Asymptomatic patients may not require therapy and are managed by ‘watching and waiting’. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement,
bone marrow failure or compression syndromes. In follicular lymphoma, the options are:

- **Radiotherapy.** This can be used for localised stage I disease, which is rare. FDG PET-CT-confirmed stage I disease has a 70% cure rate with radiotherapy.

- **Chemotherapy.** Most patients will respond to oral therapy with chlorambucil, which is well tolerated, but not curative and is reserved nowadays for older/frail patients. More intensive intravenous chemotherapy in younger patients produces better quality of life through long periods of remission.

- **Monoclonal antibody therapy.** Humanised monoclonal antibodies (‘biologic therapy’; p. 945) can be used to target surface antigens on tumour cells and to induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone, and acts synergistically when given with chemotherapy. Rituximab (R) in combination with cyclophosphamide, vincristine and prednisolone (R-CVP), cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin), prednisolone (R-CHOP) or bendamustine (R-bendamustine) is commonly used as first-line therapy. Two years of maintenance therapy with single-agent rituximab, following achievement of first or second response, especially if this is only a partial response, delays the time to next treatment. As yet, however, rituximab maintenance has not shown a survival benefit. New and more potent monoclonal antibodies are in development: a recent trial of obinutuzumab combined with chemotherapy showed longer progression-free survival compared to similar chemotherapy with rituximab.

- **Targeted therapy.** The PI3 kinase inhibitor idelalisib is approved for relapsed follicular lymphoma and ibrutinib (Fig. 25.30) is approved for relapsed mantle cell lymphoma (a poor-prognosis lymphoma with low-grade histology, but aggressive clinical behaviour) and for relapsed Waldenström’s macroglobulinaemia (also known as lymphoplasmacytic lymphoma, see below). Newer targeted therapies are likely to become more widely used in low-grade lymphomas in the near future.

- **Transplantation.** High-dose chemotherapy and autologous HSCT can produce long remissions in patients with relapsed disease. Decisions on the timing of such treatment are complex in the context of rituximab maintenance and newer targeted therapies. However, younger patients with short first or second remissions or who relapse during rituximab maintenance should be considered.

### High-grade NHL

Patients with diffuse large B-cell NHL need treatment at initial presentation:

- **Chemotherapy.** The majority (>90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin) and prednisolone).

- **Monoclonal antibody therapy.** When combined with CHOP chemotherapy, rituximab (R) increases the complete response rates and improves overall survival. R-CHOP, 4–6 cycles, is currently recommended as first-line therapy for all relatively fit patients. Dose reduction (R-mini CHOP) is preferable in those over 80 years of age and replacement of doxorubicin with gemcitabine (R-GCVP) is considered in those with impaired cardiac function.

- **Radiotherapy.** Stage I patients without bulky disease are treated with four cycles of CHOP or R-CHOP, followed by involved site radiotherapy. Radiotherapy is also indicated for a residual localised site of bulk disease after chemotherapy and for spinal cord and other compression syndromes.

- **HSCT.** Autologous HSCT (p. 945) benefits patients with relapsed disease that is sensitive to salvage immunochemotherapy. As with HL, achieving a negative FDG PTC-CT negativity to autologous transplantation is desirable.

- **CAR-T-cell therapy** (Fig. 25.17) is licensed for certain patients with multiply relapsed DLBCL or high-grade transformation of follicular lymphoma and can salvage patients from a desperate situation.

### Prognosis

Low-grade NHL runs an indolent remitting and relapsing course, with an overall median survival of 12 years. Transformation to a high-grade NHL occurs in 3% per annum and is associated with poor survival.

In diffuse large B-cell NHL treated with R-CHOP, some 75% of patients overall respond initially to therapy and 50% will have disease-free survival at 5 years. The prognosis for patients with high grade NHL is further refined according to the international prognostic index (IPI). For high-grade NHL, 5-year survival ranges from over 75% in those with low-risk scores (age <60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Rearrangements of the c-MYC oncogene, either alone (more commonly Burkitt lymphoma) or with rearrangements of BCL-2 and/or BCL-6 (double or triple hit high-grade lymphomas) are recognised entities in WHO classification with poor prognoses and are increasingly treated more aggressively.

Relapse is associated with a poor response to further chemotherapy (<10% 5-year survival), but in patients under 65 years HSCT improves survival.

### Paraproteinaemias

A gammopathy refers to over-production of one or more classes of immunoglobulin. It may be polyclonal in association with acute or chronic inflammation, such as infection including HIV, sarcoidosis, autoimmune disorders or some malignancies. Alternatively, a monoclonal increase in a single immunoglobulin class may occur in association with normal or reduced levels of the other immunoglobulins. Such monoclonal proteins (also called M-proteins, paraproteins or monoclonal gammopathies) occur as a feature of myeloma, solitary plasmacytomas, lymphoma and amyloidosis, in connective tissue disease such as rheumatoid arthritis or polymyalgia rheumatica, in infection such as HIV and in solid tumours. In addition, they may be present with no underlying disease. Gammopathies are detected by plasma immunoelctrophoresis.

### Monoclonal gammopathy of uncertain significance

In monoclonal gammopathy of uncertain significance (MGUS, also known as benign monoclonal gammopathy), a paraprotein is present in the blood but there are no other features of myeloma, Waldenström macroglobulinaemia (see below), lymphoma or related disease. It is a common condition associated with increasing age; a paraprotein can be found in 1% of the population aged over 50 years, increasing to 5% over 80 years.

### Clinical features and investigations

Patients are usually asymptomatic and the paraprotein is found on blood testing for other reasons. The routine blood count and biochemistry are normal, the paraprotein is usually present in small amounts with no associated immune paresis and there are no lytic bone lesions. The bone marrow may have increased plasma cells, but these usually constitute less than 10% of nucleated cells.

### Prognosis

After follow-up of 20 years, only one-quarter of cases will progress to myeloma or a related disorder (i.e. around 1% per annum). There is no certain way of predicting progression in an individual patient. However, an abnormal ratio of kappa to lambda light chains (serum free light chain ratio, SFLR) increases the risk of progression. Patients with an abnormal ratio should be monitored for progression on an annual basis.
Waldenström macroglobulinaemia

This is a low-grade lymphoplasmacytic lymphoma associated with an IgM paraprotein, causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in old age and more commonly affects males.

Patients classically present with features of hyperviscosity, such as nosebleeds, bruising, delirium and visual disturbance. However, presentation is more commonly with anaemia, systemic symptoms, splenomegaly or lymphadenopathy, or may be asymptomatic with an IgM paraprotein detected on routine screening. Patients are found on investigation to have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells, plasma cells and sometimes prominent mast cells. A high proportion of patients have a mutation in the MYD88 gene.

Management

If patients show symptoms of hyperviscosity and anaemia, plasmapheresis is required to remove IgM and make blood transfusion possible. Chemotherapy with alkylating agents, such as chlorambucil, has historically been the mainstay of treatment, controlling disease in over 50%. Fludarabine may be more effective in this disease, but has more side-effects. Rituximab in combination with chemotherapy, e.g. bendamustine, is now most commonly used; ibritumomab is very effective and has recently been licensed for use. Rituximab alone can cause a rapid release of IgM and increase in viscosity. The median survival is 5 years.

Multiple myeloma

This is a malignant proliferation of plasma cells. Normal plasma cells are derived from B cells and produce immunoglobulins that contain heavy and light chains. Normal immunoglobulins are polyclonal, which means that a variety of heavy chains are produced and each may be of kappa or lambda light chain type (Ch. 4). In myeloma, plasma cells produce immunoglobulin of a single heavy and light chain, a monoclonal protein commonly referred to as a paraprotein. In most cases an excess of light chain is produced and in some cases only light chain is produced; this appears in the urine as Bence Jones proteinuria and can be measured in the urine or serum as free light chain. The frequency of different isotypes of monoclonal protein in myeloma is shown in Box 25.58.

Although a small number of malignant plasma cells are present in the circulation, the majority are present in the bone marrow. The malignant plasma cells produce cytokines, which stimulate osteoclasts and result in net bone reabsorption. The resulting lytic lesions cause bone pain, fractures and hypocalcaemia. Marrow involvement can result in anaemia or pancytopenia.

Clinical features and investigations

The incidence of myeloma is 4/100,000 new cases per annum, with a male-to-female ratio of 2:1. The median age at diagnosis is 60–70 years and the disease is more common in people of African Caribbean origin. The clinical features are demonstrated in Fig. 25.37.

Diagnosis of myeloma requires two of the following criteria to be fulfilled:

- increased malignant plasma cells in the bone marrow
- serum and/or urinary M-protein
- skeletal lytic lesions.

Bone marrow aspiration, plasma and urine electrophoresis, and a skeletal survey are thus required; the latter is classically a series of plain X-rays, but more often now low-dose CT scan or whole-body MRI is performed. Normal immunoglobulin levels, i.e. the absence of immunopaenia, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR, but this is a non-specific test; only approximately 5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma. Serum albumin and β2-microglobulin are measured for prognostic purposes, along with a cytogenetic analysis of the tumour cells.

Management

If patients are asymptomatic with no evidence of end-organ damage (e.g. to kidneys, bone marrow or bone), treatment may not be required. So-called asymptomatic myeloma should be monitored closely for the development of end-organ damage.

Immediate support

- High fluid intake to treat renal impairment and hypercalcaemia (p. 676)
- Analgesia for bone pain
- Bisphosphonates for hypercalcaemia and to delay other skeletal-related events (p. 1051)
- Allopurinol to prevent urate nephropathy
- Plasmapheresis, if necessary, for hyperviscosity
- Antibiotic prophylaxis with levofloxacin during the first 3 months of therapy.

Chemotherapy with or without HSCT

Patients are initially assessed for their fitness and eligibility for autologous HSCT and treatment pathways vary accordingly. Myeloma therapy has improved with the addition of novel agents, initially the immunomodulatory drug thalidomide and more recently the proteasome inhibitors bortezomib and carfilzomib, the second- and third-generation immunomodulatory drugs lenalidomide and pomalidomide and the anti-myeloma antibodies daratumumab and isatuximab, which binds to CD 38 on the malignant plasma cell (Fig. 25.38).

For first-line therapy in older patients who are unsuitable for transplant, thalidomide combined with the alkylating agent melphalan and prednisolone (MPT) has increased the median overall survival to more than 4 years. Lenalidomide is approved first-line treatment for patients not eligible for transplantation and who are intolerant of, or unsuitable for, thalidomide. Thalidomide and lenalidomide both have anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. Both can cause somnolence, constipation, peripheral neuropathy and thrombosis, though lenalidomide has a better side-effect profile. It is vital that females of child-bearing age use adequate contraception, as thalidomide and lenalidomide are teratogenic. Treatment is administered until paraprotein levels have stopped falling. This is termed ‘plateau phase’ and can last for weeks or years.

In younger, fitter patients considered eligible for transplant, standard treatment includes first-line therapies, such as cyclophosphamide, thalidomide and dexamethasone (CTD) or bortezomib (Velcade), thalidomide and dexamethasone (VTD) to maximum response, and then autologous HSCT. This improves quality of life and prolongs survival, but does not cure myeloma. In all patients who have achieved maximal response, lenalidomide maintenance has been shown to prolong the response.

When myeloma progresses, treatment is given to induce a further plateau phase. In the UK, the proteasome inhibitor bortezomib and lenalidomide have been used as second- and third-line therapy, as appropriate. However, as they have been used more frequently in the first or second line with prognostic benefit, subsequent relapses are more difficult to treat. Pomalidomide, carfilzomib and daratumumab show promise in relapsed/refractory disease and are increasingly used. Patients who respond may benefit from a second autologous HSCT.
**Haematological malignancies**

**Myeloma**

**Fig. 25.37** Clinical and laboratory features of multiple myeloma. (ESR = erythrocyte sedimentation rate; NSAIDs = non-steroidal anti-inflammatory drugs)

**Chemotherapy**
- Steroids
- Melphalan
- Anthracyclins
- Platinum-based drugs

**Immune modulators (IMIDs)**
- Thalidomide
- Lenalidomide
- Pomalidomide

**Targeted antibodies/small molecules**
- Anti-CD38: daratumumab, isatuximab
- Anti-SLAMF7: elotuzumab
- Histone deacetylase inhibitor: panobinostat

**Proteosome inhibitors**
- Bortezomib
- Carfilzomib
- Ixazomib

**Bisphosphonates**

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone and may cause apoptosis of malignant plasma cells. There is evidence that intravenous zoledronic in combination with anti-myeloma therapy confers a survival advantage over oral bisphosphonates. Osteonecrosis of the jaw may be associated with long-term use or poor oral hygiene and gum sepsis; regular dental review, including a check before starting therapy, is therefore important.

**Prognosis**

The international staging system (ISS) identifies poor prognostic features, including a high β2-microglobulin and low albumin at diagnosis (ISS stage 3, median survival 29 months). Those with a normal albumin and a low β2-microglobulin (ISS stage 1) have a median survival of 62 months. Increasingly, cytogenetic analysis is used to identify poor-risk patients, e.g. t(4;14), del(17p), t(14;16), t(14;20), non-hyperdiploidy and gain(1q). Use of autologous HSCT and new in drug therapy with the newer agents have increased survival. Over one-third of patients are now surviving for 5 years, compared with only one-quarter 10 years ago. The outlook may improve further with new drugs and combinations of treatments.

Some general considerations regarding haematological malignancy in old age are summarised in Box 25.59.

**Solitary plasmacytomas**

These are rare presentations of plasma cell malignancy in which an isolated tumour occurs in soft tissues or bone. Two-thirds of cases occur in soft tissues and are commonly centred around the upper aero-digestive tract, but can occur anywhere. Others present as bone tumours,
commonly in long bones and vertebrae. Patients present with pain, palpable lumps or compression symptoms, such as difficulty swallowing, shortness of breath or cord compression.

Diagnosis involves tissue biopsy, which demonstrates a solid tumour of monoclonal plasma cells, and staging to exclude disseminated multiple myeloma. Some cases are associated with a low-level paraprotein, but other features of myeloma are absent.

Primary treatment is usually with radiotherapy. This can be curative, especially in soft tissue plasmacytomas, which less frequently progress to myeloma. Plasmacytomas of bone have a high rate of progression to myeloma and must be monitored carefully or treated as myeloma from the outset. Rarely myeloma presents as multiple plasmacytomas of bone.

Histiocytic disorders

These are a group of rare tissue infiltrating conditions affecting children and less commonly adults. Histiocytes are immune cells found in various tissues throughout the body whose functions include phagocytosis (tissue macrophages), activation of the immune system and promoting immune tolerance via antigen presentation to T cells (Fig. 25.39). Disorders resulting from pathological infiltration of tissues by histiocytes are shown in Box 25.60.

LCH is the commonest type and is caused by mutations in cell signalling known as the MAPKinase pathway. Key genes mutated in this pathway include BRAF (65%–70%) and MAP2K (20%). LCH can present with isolated painless lumps, e.g. of bone (eosinophilic granuloma) or with symptoms of disseminated tissue involvement including bone, lung, skin (e.g. persistent nappy rash), lymphadenopathy, splenomegaly and periodicontal disease. Diagnosis can be difficult because of the rarity and multiple symptoms at presentation. Management includes surgical excision or radiotherapy of an isolated lesion or topical or systemic chemotherapy drugs, including methotrexate, etoposide and cladribine in disseminated LCH. The BRAF inhibitors, e.g. vemurafenib, have shown promising activity in relapsed LCH.

HLH results from mutations in immune genes, e.g. perforin. Presentation is predominantly in children with tissue infiltration by histiocytes and macrophages. Abnormal cytokine production, e.g. interferon-gamma and activation of complement, leads to hyperinflammation and associated haemophagocytosis of blood cells producing pancytopenia. Treatment is based around immunosuppression with glucocorticoids, chemotherapy or ciclosporin, all with the aim of proceeding to allogeneic stem cell transplantation. Newer treatments aimed at inhibiting cytokines or complement activation are being studied.

An acquired form of reactive haemophagocytosis called macrophage activation syndrome (MAS) or secondary HLH is associated with a range of conditions including rheumatological conditions, e.g. juvenile idiopathic arthritis, SLE and Kawasaki disease, acute viral infections, e.g. EBV, CMV and HHV6 and T-cell lymphomas. These diverse conditions generate a cytokine storm, which drives the MAS. Patients present very unwell with fever, severe pancytopenia, deranged coagulation tests, hepatomegaly and a very high ferritin level (often measured in the tens of thousands μg/L). Management includes supportive care, glucocorticoids or other immunosuppression, inhibition of IL-1 with anakinra and, if possible, treatment of the underlying condition.

Aplastic anaemia

Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum. The disease is much more common
Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly, infections. An FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. Bone marrow aspiration and trephine reveal hypocellularity. The severity of aplastic anaemia is graded according to the Camitta criteria (Box 25.61).

Management

All patients will require blood product support and aggressive management of infection. The prognosis of severe aplastic anaemia managed with supportive therapy only is poor and more than 50% of patients die, usually in the first year. The curative treatment for patients under 35 years of age with severe idiopathic aplastic anaemia is allogeneic HSCT if there is an available sibling donor (p. 945). Patients aged 35–50 may be candidates if they have no comorbidities. Those with a compatible sibling donor should proceed to transplantation as soon as possible; they have a 75%–90% chance of long-term cure. In older patients and those without a suitable donor, immunosuppressive therapy (IST) with anti-thymocyte globulin (ATG) and ciclosporin is the treatment of choice and gives 5-year survival rates of 75%. Unrelated donor allografts are considered for suitable patients who fail IST. The thrombopoietin receptor agonist eltrombopag has produced thrombocytopenia in patients who fail IST and is licensed for this indication. Non-transplanted patients may relapse or other clonal disorders of haematopoiesis may evolve, such as paroxysmal nocturnal haemoglobinuria (p. 959), myelodysplastic syndrome (p. 970) and AML (p. 964). Patients with aplastic anaemia must be followed up long-term.

Secondary aplastic anaemia

Causes of this condition are listed in Box 25.62. It is not practical to list all the drugs that have been suspected of causing aplasia. It is important to check the reported side-effects of all drugs taken over the preceding months. In some instances, the cytopenia is more selective and affects only one cell line, most often the neutrophils. Frequently, this is an incidental finding, with no ill health. It probably has an immune basis, but this is difficult to prove.

The clinical features and methods of diagnosis are the same as for primary idiopathic aplastic anaemia. An underlying cause should be treated or removed, but otherwise management is as for the idiopathic form.

Myeloproliferative neoplasms

These make up a group of chronic conditions characterised by clonal proliferation of marrow stem/precursor cells. Polycythaemia rubra vera (PRV), essential thrombocythaemia and myelofibrosis are the non- leukaemic myeloproliferative neoplasms. Although the majority of patients are classifiable as having one of these disorders, some have overlapping features and there is often progression from one to another, e.g. PRV to myelofibrosis. A mutation in the gene on chromosome 9 encoding the signal transduction molecule JAK-2 (JAK-2 V617F) has been found in more than 90% of PRV cases and 50% of those with essential thrombocythaemia and myelofibrosis; less frequently, mutations may be identified in exon 12 of JAK-2. Mutations in the calreticulin gene (CALR), which produces a chaperone protein that protects proteins moving from the endoplasmic reticulum to the cytoplasm, have been found in a further 25% of patients with essential thrombocythaemia. Less commonly, mutations can be detected in the thrombopoietin receptor gene MPL.

Myelofibrosis

In myelofibrosis, the marrow is initially hypercellular, with an excess of abnormal megakaryocytes that release growth factors, such as platelet-derived growth factor, to the marrow microenvironment, resulting in a reactive proliferation of fibroblasts. As the disease progresses, the marrow becomes fibrosed.

Most patients present over the age of 50 years, with lassitude, weight loss and night sweats. The spleen can be massively enlarged due to extramedullary haematopoiesis (blood cell formation outside the bone marrow), and painful splenic infarcts may occur.

The characteristic blood picture is leukocytosis and anaemia, with circulating immature red blood cells (increased reticulocytes and nucleated red blood cells) and granulocyte precursors (myelocytes). The red cells are shaped like teardrops (teardrop poikilocytes), and giant platelets may be seen in the blood. The white count varies from low to moderately high and the platelet count may be high, normal or low. Urate levels may be high due to increased cell breakdown, and folate deficiency is common. The marrow is often difficult to aspirate and a trephine biopsy shows an excess of megakaryocytes, increased reticulin and fibrous tissue replacement. The presence of a pathological JAK-2 mutation supports the diagnosis.

Management and prognosis

Median survival is 4 years from diagnosis, but ranges from 1 year to over 20 years. Treatment is directed at control of symptoms, e.g. red cell transfusions for anaemia. Folic acid should be given to prevent deficiency. Cytotoxic therapy with hydroxyurea may help control spleen size, the white cell count or systemic symptoms. Splenectomy...
may be required for a grossly enlarged spleen or symptomatic pancytopenia secondary to splenic pooling of cells and hypersplenism. Allogeneic HSCT may be considered for younger patients. Ruxolitinib, an inhibitor of JAK-2, is effective at reducing systemic symptoms and splenomegaly and may improve life expectancy with longer-term use.

Essential thrombocythaemia

Uncontrolled proliferation of megakaryocytes results in a raised level of circulating platelets that are often dysfunctional. Prior to a diagnosis of essential thrombocythaemia being made, reactive causes of thrombocytosis must be excluded (see Box 25.15). The presence of pathogenic JAK-2 V617F, CALR or, rarely, MPL mutations supports the diagnosis, but is not universal. Patients present at a median age of 60 years with vascular occlusion, acrocyanosis (painful discoloured finger tips) or bleeding, or with an asymptomatic isolated raised platelet count. A small percentage (around 5%) will transform to acute leukaemia and others to myelofibrosis.

It is likely that most patients with essential thrombocythaemia benefit from low-dose aspirin to reduce the risk of occlusive vascular events. Low-risk patients (age <40 years, platelet count <1500 x 10^9/L and no bleeding or thrombosis) may not require treatment to reduce the platelet count. For those with a platelet count above 1500 x 10^9/L, with symptoms, or with other risk factors for thrombosis such as diabetes or hypertension, treatment to control platelet counts should be given. Agents include oral hydroxycarbamide or anagrelide, an inhibitor of megakaryocyte maturation. Intravenous radioactive phosphorus (32P) may be useful in old age, but is rarely available nowadays, and interferon-alfa has a role in younger patients, including pregnant women and women planning to conceive.

Polycythaemia rubra vera

PRV occurs mainly in patients over the age of 40 years and presents either as an accidental finding of a high haemoglobin, or with symptoms of hyperviscosity, such as lassitude, loss of concentration, headaches, dizziness, blackouts, pruritus and epistaxis. Some patients present with manifestations of peripheral arterial or cerebrovascular disease. Venous thromboembolism may also occur. Peptic ulceration is common, sometimes complicated by bleeding. Patients are often plethoric and many have a palpable spleen at diagnosis.

Investigation of polycythaemia is discussed on page 933. The diagnosis of PRV now rests on the demonstration of a high haematocrit and the presence of a pathogenic JAK2 mutation (positive in 95% of cases). In the occasional JAK2-negative cases, a raised red cell mass and absence of causes of a secondary erythrocytosis must be established. The spleen may be enlarged and neutrophil and platelet counts are frequently raised, an abnormal karyotype may be found in the marrow and in vitro culture of the marrow can be used to demonstrate autonomous growth in the absence of added growth factors.

Management and prognosis

Aspirin reduces the risk of thrombosis. Venesection gives prompt relief of hyperviscosity symptoms. Between 400 and 500 mL of blood (less if the patient is in old age) are removed and the venesection is repeated every 5–7 days until the haematocrit is reduced to below 45%. Less frequent, regular venesection will maintain this level until the haemoglobin remains reduced because of iron deficiency.

Suppression of marrow proliferation with hydroxycarbamide or interferon-alfa may reduce the risk of vascular occlusion, control spleen size and reduce transformation to myelofibrosis. The JAK-2 inhibitor ruxolitinib is licensed for patients whose disease is not controlled by hydroxycarbamide. Median survival after diagnosis in treated patients exceeds 10 years. Some patients survive more than 20 years; however, cerebrovascular or coronary events occur in up to 60% of patients. The disease may convert to another myeloproliferative disorder, with about 15% developing acute leukaemia or myelofibrosis.

Bleeding disorders

Disorders of primary haemostasis

The initial formation of the platelet plug (see Fig. 25.6A; also known as ‘primary haemostasis’) may fail in thrombocytopenia (p. 938), von Willebrand disease (p. 984), and also in platelet function disorders and diseases affecting the vessel wall.

Vessel wall abnormalities

Vessel wall abnormalities may be:

- congenital, such as hereditary haemorrhagic telangiectasia
- acquired, as in a vasculitis (Ch. 26) or scurvy.

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited condition caused by mutations in the genes encoding endoglin and activin receptor-like kinase, which are endothelial cell receptors for transforming growth factor-beta (TGF-β), a potent angiogenic cytokine. Telangiectasia and small aneurysms are found on the fingertips, face and tongue, and in the nasal passages, lung and gastrointestinal tract. A significant proportion of these patients develop larger pulmonary arteriovenous malformations (PAVMs) that cause arterial hypoxaemia due to a right-to-left shunt. These predispose to paradoxical embolism, resulting in stroke or cerebral abscess. All patients with HHT should be screened for PAVMs and cerebral AVMs; if these are found, ablation by embolisation should be considered.

Patients present either with recurrent bleeds, particularly epistaxis, or with iron deficiency due to occult gastrointestinal bleeding. Treatment can be difficult because of the multiple bleeding points, but regular iron therapy often allows the marrow to compensate for blood loss. Local cautery or laser therapy may prevent single lesions from bleeding. A variety of medical therapies have been tried but none has been found to be universally effective.

Ehlers–Danlos disease

Vascular Ehlers–Danlos syndrome (type 4) is a rare autosomal dominant disorder (1/100,000) caused by a defect in type 3 collagen that results in fragile blood vessels and organ membranes, leading to bleeding and organ rupture. Classical joint hypermobility (Ch. 26) is often limited in this form of the disease, but skin changes and facial appearance are typical. The diagnosis should be considered when there is a history of bleeding with normal laboratory tests.

Scurvy

Vitamin C deficiency affects the normal synthesis of collagen and results in a bleeding disorder characterised by perifollicular and petechial haemorrhage, bruising and subperiosteal bleeding. The key to diagnosis is the dietary history (Ch. 22).

Platelet function disorders

Bleeding may result from thrombocytopenia (see Box 25.14) or from congenital or acquired abnormalities of platelet function. The most common acquired disorders are iatrogenic, resulting from the use of aspirin, clopidogrel, ticagrelor, dipyrudamole and the glycoprotein IIb/IIIa inhibitors to prevent arterial thrombosis (see Box 25.26). Inherited platelet function abnormalities are relatively rare. Congenital abnormalities may be due to deficiency of the membrane glycoproteins, e.g. Glanzmann’s thrombasthenia (IIb/IIIa) or Bernard–Soulier syndrome (IIb), or due to the presence of defective platelet granules, e.g. a deficiency of dense (delta) granules (see Fig. 25.7) giving rise to storage pool disorders. The congenital macrothrombocytopenopathies that are due to mutations in the myosin heavy chain gene MYH-9 are characterised by large platelets, inclusion bodies...
in the neutrophils (Döhle bodies) and a variety of other features, including sensorineural deafness and renal abnormalities. Other familial thrombocytopenias are important, as they can be associated with somatic features (TAR; thrombocytopenia with absent radii [TAR]), and some are associated with a propensity for development of bone marrow failure or dysplasia (e.g., mutations in RUNX-1 and ANKRD 26).

Apart from Glanzmann’s thrombasthenia, these conditions are mild disorders, with bleeding typically occurring after trauma or surgery, but rarely spontaneous. Glanzmann’s thrombasthenia is an autosomal recessive condition associated with a variable, but often severe bleeding disorder. These conditions are usually managed by local mechanical measures, but antifibrinolics, such as tranexamic acid, may be useful and, in severe bleeding, platelet transfusion may be required. Recombinant Vlla is licensed for the treatment of resistant bleeding in Glanzmann’s thrombasthenia.

## Thrombocytopenia

Thrombocytopenia occurs in many disease processes, as listed in Box 25.14, many of which are discussed elsewhere in this chapter.

### Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is immune-mediated with involvement of autoantibodies, most often directed against the platelet membrane glycoprotein Ib/IIa, which sensitize the platelet, resulting in premature removal from the circulation by cells of the reticuloendothelial system. It is not a single disorder; some cases occur in isolation while others are associated with underlying immune dysregulation in conditions such as connective tissue diseases, HIV infection, B-cell malignancies, pregnancy and certain drug therapies. The clinical presentation and pathogenesis are similar, whatever the cause of ITP.

### Clinical features and investigations

The presentation depends on the degree of thrombocytopenia. Spontaneous bleeding typically occurs only when the platelet count is below 20 × 10⁹/L. At higher counts, the patient may complain of easy bruising or sometimes epistaxis or menorrhagia. Many cases with counts of more than 50 × 10⁹/L are discovered by chance.

In adults, ITP more commonly affects females and may have an insidious onset. Unlike ITP in children, it is unusual for there to be a history of a preceding viral infection. The development of ITP in the context of COVID-19 infection has been documented. Symptoms or signs of a connective tissue disease may be apparent at presentation or emerge several years later. Patients aged over 65 years should be considered for a bone marrow examination to look for an accompanying B-cell malignancy and appropriate autoantibody testing performed if a diagnosis of connective tissue disease is suspected. HIV testing should be considered because a positive result will have major implications for appropriate therapy. The peripheral blood film is normal, apart from a greatly reduced platelet number, while the bone marrow reveals an obvious increase in megakaryocytes.

### Management

Many patients with stable compensated ITP and a platelet count of more than 30 × 10⁹/L do not require treatment to raise the platelet count, except at times of increased bleeding risk, such as surgery and biopsy. First-line therapy for patients with spontaneous bleeding is with high doses of glucocorticoids, either prednisolone (1 mg/kg daily) or dexamethasone (40 mg daily for 4 days), to suppress antibody production and inhibit phagocytosis of sensitised platelets by reticuloendothelial cells. Administration of intravenous immunoglobulin can raise the platelet count by blocking antibody receptors on reticuloendothelial cells and is combined with glucocorticoid therapy if there is severe haemostatic failure, especially with evidence of significant mucosal bleeding or a slow response to glucocorticoids alone. Persistent or potentially life-threatening bleeding should be treated with platelet transfusion in addition to the other therapies.

The condition may become chronic, with remissions and relapses. Relapses should be treated by re-introducing glucocorticoids. If a patient has two relapses or primary refractory disease, second-line therapies are considered. The options for second-line therapy include the thrombopoietin receptor agonists (TPO-RA) eltrombopag and romiplostim (which stimulate new platelet formation), the splenic tyrosine kinase inhibitor fostamatinib, splenectomy and immunosuppression. Where splenectomy is considered, the precautions shown in Box 25.37 need to be in place. Splenectomy produces complete remission in about 70% of patients and improvement in a further 20%–25% in favourable cases. The TPO-RAs induce response in around 75% of cases, usually within 10–14 days. Low-dose glucocorticoid therapy and immunosuppressants such as rituximab, ciclosporin, mycophenolate and tacrolimus may also produce remissions. The order in which therapies should be used is not entirely clear, although the TPO-RAs and fostamatinib are licensed for this indication, while the immunosuppressive agents are not.

### Coagulation disorders

Normal coagulation is explained in Figure 25.6 and the effects of age are discussed in Box 25.63. Coagulation factor deficiency may be congenital or acquired and may affect one or several of the coagulation factors (Box 25.64). Inherited disorders are almost uniformly related to decreased synthesis, as a result of mutation in the gene encoding a key protein in coagulation. Von Willebrand disease is the most common inherited bleeding disorder. Haemophilia A and B are the most common single coagulation factor deficiencies, but inherited deficiencies of all the other coagulation factors are seen. Acquired disorders may be due to under-production (e.g., in liver failure), increased consumption (e.g., in DIC) or inhibition of function of coagulation factors (such as heparin therapy or immune inhibitors of coagulation, e.g., acquired haemophilia A).

### Haemophilia A

Factor VIII deficiency resulting in haemophilia A affects 1/10'000 individuals. It is the most common congenital coagulation factor deficiency. Factor VIII is primarily synthesised by the liver and endothelial cells and has a half-life of about 12 hours. It is protected from proteolysis in the circulation by binding to von Willebrand factor (vWF).

### Genetics

The factor VIII gene is located on the X chromosome. Haemophilia is associated with a range of mutations in the factor VIII gene; these include major inversions, large deletions and missense, nonsense and splice site abnormalities. As the factor VIII gene is on the X chromosome, haemophilia A is a sex-linked disorder (Ch. 9). Thus all daughters of a patient with haemophilia are obligate carriers and they, in turn, have a 1 in 4 chance of each pregnancy resulting in the birth of an affected male baby, a normal male baby, a carrier female or a normal female. Antenatal diagnosis by chorionic villous sampling is possible in families with a known mutation.

Haemophilia ‘breeds true’ within a family; all members have the same factor VIII gene mutation and a similarly severe or mild phenotype. Female carriers of haemophilia may have reduced factor VIII levels because of random inactivation of their normal X chromosome in the developing fetus. This can result in a mild bleeding disorder; thus all known or suspected carriers of haemophilia A should have their factor VIII level measured.

### Clinical features

The extent and patterns of bleeding are closely related to residual factor VIII levels (Box 25.65). Patients with severe haemophilia (factor VIII levels <0.01 U/mL) present with spontaneous bleeding into skin, muscle and joints. Retropertitoneal and intracranial bleeding is also a feature. Babies with severe haemophilia have an increased risk of intracranial haemorrhage and, although there is insufficient evidence to recommend routine
25.33 Haemostasis and thrombosis in old age

- Thrombocytopenia: reasonably common because of the rising prevalence of disorders in which it may be a secondary feature and also because of the greater use of drugs that can cause it.

- 'Senile' purpura: presumed to be due to an age-associated loss of subcutaneous fat and the collagenous support of small blood vessels, making them more prone to damage from minor trauma.

- Thrombosis: incidence of thromboembolic disease rises with increasing age. This may be due to stasis and concurrent illness, to which older people are prone. Some studies show increased platelet aggregation with age and others age-associated hyperactivity of the haemostatic system, which could contribute to a prothrombotic state.

- Thromboprophylaxis: should be considered in all older patients who are immobile as a result of acute illness. Prophylaxis is not required in chronic immobility without a medical cause, as there is no associated increase in thromboembolism.

- Anticoagulation: older patients are more sensitive to the anticoagulant effects of warfarin, partly due to the concurrent use of other drugs and the presence of other pathology. Life-threatening or fatal bleeds on warfarin are significantly more common in those over 80 years.

25.64 Causes of coagulopathy

Congenital

X-linked
- Haemophilia A and B

Autosomal
- Von Willebrand disease
- Factor II, V, VII, X, XI and XIII deficiencies
- Combined II, VII, IX and X deficiency
- Combined V and VIII deficiency
- Hypofibrinogenaemia
- Dysfibrinogenaemia

Acquired

Under-production
- Liver failure
- Vitamin K deficiency

Increased consumption
- Coagulation activation: Disseminated intravascular coagulation (DIC)
- Immune-mediated: Acquired haemophilia and von Willebrand syndrome

Drug-induced
- Inhibition of function: Heparins Argatroban Bivalirudin Fondaparinux Rivaroxaban Apixaban Dabigatran Edoxaban
- Inhibition of post-translational modification: Warfarin

The major morbidity of recurrent bleeding in severe haemophilia is musculoskeletal. Bleeding is typically into large joints, especially knees, elbows, ankles and hips. Muscle haematomas are also characteristic, most commonly in the calf and psoas muscles. If early treatment is not given to arrest bleeding, a hot, swollen and very painful joint or muscle haematoma develops. Recurrent bleeding into joints leads to synovial hypertrophy, destruction of the cartilage and chronic haemophilic arthropathy (Fig. 25.40). Complications of muscle haematomas depend on their location. A large psoas bleed may extend to compress the femoral nerve; calf haematomas may increase pressure within the inflexible fascial sheath, causing a compartment syndrome with ischaemia, necrosis, fibrosis, and subsequent contraction and shortening of the Achilles tendon.

Management

The aim of management of severe haemophilia A (and B; see below) in high-income countries is to render patients ‘bleed free’. This can be achieved by prophylaxis using coagulation factor concentrates or, in haemophilia A, by a bispecific monoclonal antibody called emicizumab that mimics factor VIII activity. Emicizumab binds to both activated factor IX and factor X to allow the formation of the tenase complex that results in thrombin and clot formation (Fig. 25.41). Prophylaxis using concentrates aims to achieve trough levels of factor VIII or IX that protect the patient against spontaneous bleeding. There is debate about optimal trough values needed to achieve this aim. Prophylaxis can be provided in many different ways: daily, on alternate days, or on information from pharmaco-kinetic studies that inform on the best way of scheduling prophylaxis. Practice in haemophilia A and B is also changing due to the introduction of recombinant factor concentrates that have been manipulated to alter their half-life. In addition to standard half-life recombinant factor VIII and IX, there are new products produced by FC fusion and pegylation/glycoPEGylation that extend the half-life of the coagulation factor to the degree that it can be used to alter dosing schedules for prophylaxis.

The alternative approach, which still needs to be used in low- and middle-income countries, is to treat on demand. In severe haemophilia A, bleeding episodes should be treated by raising the factor VIII level, usually by intravenous infusion of factor VIII concentrate. Factor VIII concentrates are freeze-dried and stable at 4°C and can therefore be stored in domestic refrigerators, allowing patients to treat themselves at home at the earliest indication of bleeding. Coagulation factor concentrates prepared from blood donor plasma are now screened for many blood-borne pathogens including HBV, HCV and HIV, and undergo two separate virus inactivation or removal processes during manufacture; these preparations have a good safety record. However, factor concentrates prepared by recombinant technology are now widely available and, although more expensive, are perceived as being safer than those derived from human plasma in relation to infection risk. In addition to raising factor VIII or IX concentrations, resting of the bleeding site with either bed rest or a splint reduces continuing haemorrhage. Once bleeding has settled, the patient should be mobilised and physiotherapy used to restore strength to the surrounding muscles. All non-immune potential recipients of pooled blood products should be offered hepatitis A and B immunisation.

caesarean section for these births, it is appropriate to avoid head trauma and to perform cranial imaging of the newborn within the first 24 hours of life. Individuals with moderate and mild haemophilia (factor VIII levels 0.01–0.4 U/mL) present with the same pattern of bleeding, but usually after trauma or surgery when bleeding is disproportionate to the severity of the insult.

- **Emicizumab** – replaces function of factor VIII in the tenase complex
- **High-weight vWF multimers in TTP**
- **Caplacizumab** – binds the A1 domain of vWF preventing platelet binding

The vasopressin receptor agonist desmopressin raises the vWF and factor VIII levels 3–4-fold, which is useful in arresting bleeding in patients with mild or moderate haemophilia A. The dose required for this purpose is higher than that used in diabetes insipidus, usually 0.3 μg/kg, and is given intravenously or subcutaneously. Alternatively, the same effect can be achieved by intranasal administration of a 300 μg dose. Following repeated administration of desmopressin, patients need to be monitored for evidence of water retention, which can result in significant hyponatraemia. Desmopressin is contraindicated in patients with a history of severe arterial disease, because of a propensity to provoke a thrombotic event, and in young children where hyponatraemia can result in fits.

**Complications of coagulation factor therapy**

Before 1986, coagulation factor concentrates from human plasma were not fully virus-inactivated and many patients became infected with HIV and HBV/HCV. Concern that the infectious agent that causes variant Creutzfeldt–Jakob disease (vCJD) (Ch. 28) might be transmissible by blood and blood products has been confirmed in recipients of red cell transfusion (p. 940), and in one recipient of factor VIII. Another serious complication of factor VIII treatment is the development of anti-factor VIII antibodies, which arise in about 25% of those with severe haemophilia. These antibodies rapidly neutralise therapeutic infusions, making treatment relatively ineffective. Infusions of activated clotting factors, e.g.
Villa or factor VIII inhibitor bypass activity (FEIBA), may stop bleeding. Enicizumab has a major role in the treatment of patients with haemophilia A who have developed inhibitory antibodies.

**Haemophilia B (Christmas disease)**

Aberrations of the factor IX gene, which is also present on the X chromosome, result in a reduction of the plasma factor IX level, giving rise to haemophilia B. This disorder is clinically indistinguishable from haemophilia A, but is less common. The frequency of bleeding episodes is related to the severity of the deficiency of the plasma factor IX level. Treatment is with a factor IX concentrate, used in much the same way as factor VIII for haemophilia A. The new extended half-life recombinant factor IX products made by FC fusion, albumin fusion and pegylation offer the possibility of prophylaxis on a once-weekly or even two-weekly schedule. Although factor IX concentrates share the problems of virus transmission seen with factor VIII, they do not commonly induce inhibitory antibodies (<1% patients); when this does occur, however, it may be heralded by the development of a severe allergic-type reaction.

**Von Willebrand disease**

Von Willebrand disease is a common and usually mild bleeding disorder caused by a quantitative (types 1 and 3) or qualitative (type 2) deficiency of von Willebrand factor (vWF). This protein is synthesised by endothelial cells and megakaryocytes, and is involved in both platelet function and coagulation. It normally forms a multimeric structure that is essential for its interaction with subendothelial collagen and platelets (see Figs. 25.6 and 25.7). vWF acts as a carrier protein for factor VIII, to which it is non-covalently bound; deficiency of vWF lowers the plasma factor VIII level. vWF also forms bridges between platelets and subendothelial components (e.g. collagen; see Fig. 25.6B), allowing platelets to adhere to damaged vessel walls; deficiency of vWF therefore leads to impaired platelet plug formation. Blood group antigens (A and B) are expressed on vWF, reducing its susceptibility to proteolysis; as a result, people with blood group O have lower circulating vWF levels than individuals with non-O groups.

Most patients with von Willebrand disease have a type 1 disorder, characterised by a quantitative decrease in a normal functional protein. This usually arises through reduced synthesis or increased clearance of vWF. Patients with type 2 disorders inherit vWF molecules that are functionally abnormal. The type of abnormality depends on the site of the mutation in the vWF gene and how it affects binding to platelets, collagen and factor VIII. Patients with type 2A disease have abnormalities in vWF-dependent platelet adhesion; those with mutations in the platelet glycoprotein Ib binding site, resulting in increased affinity for glycoprotein Ib, have type 2B disease; those with mutations in the factor VIII binding site have type 2N disease; and those with other abnormalities in platelet binding, but with normal vWF multimeric structure, have type 2M disease. The patterns of laboratory abnormality accompanying these types are described in Box 25.66. The gene for vWF is located on chromosome 12 and the disease is usually autosomal dominantly inherited, except in type 2N and type 3, where inheritance is autosomal recessive.

**Clinical features**

Patients present with haemorrhagic manifestations similar to those in individuals with reduced platelet function. Superficial bruising, epistaxis, menorrhagia and gastrointestinal haemorrhage are common. Bleeding episodes are usually much less frequent than in severe haemophilia, and excessive haemorrhage may be observed only after trauma or surgery. Within a single family, the disease has variable penetrance, so that some members may have quite severe and frequent bleeds, whereas others are relatively asymptomatic.

**Investigations**

The disorder is characterised by reduced activity of vWF and factor VIII. The disease can be classified using a combination of assays that include functional and antigenic measures of vWF, multimeric analysis of the protein, and specific tests of function to determine binding to platelet glycoprotein Ib (RIPA) and factor VIII (see Box 25.66). In addition, analysis for mutations in the vWF gene can be informative.

**Management**

Many episodes of mild haemorrhage can be successfully treated by local means or with desmopressin, which raises the vWF level, resulting in a secondary increase in factor VIII. Tranexamic acid may be useful in mucosal bleeding. For more serious or persistent bleeds, haemostasis can be achieved with selected factor VIII concentrates, which contain considerable quantities of vWF in addition to factor VIII. Pure plasma-derived and recombinant vWF concentrates are now available, improving the options and the perceived safety of treatment. Young children and patients with severe arterial disease should not receive desmopressin, and patients with type 2B disease develop thrombocytopenia that may be troublesome following desmopressin. Bleeding in type 3 patients responds only to factor VIII/vWF concentrate.

**Rare inherited bleeding disorders**

Severe deficiencies of factor VII, X and XIII occur as autosomal recessive disorders. They are rare, but are associated with severe bleeding. Typical features include haemorrhage from the umbilical stump and intracranial haemorrhage. Factor XIII deficiency in women is typically associated with recurrent fetal loss. Factor XI deficiency may occur in heterozygous or homozygous individuals. Bleeding is very variable and is not accurately predicted by coagulation factor levels. In general, severe bleeding is confined to patients with levels below 15% of normal.

**Acquired bleeding disorders**

DIC is an important cause of bleeding that begins with exaggerated and inappropriate intravascular coagulation. It is discussed later under thrombotic disorders.

**Liver disease**

Although, traditionally, severe parenchymal liver disease is associated with an excess of bleeding, it is now clear that these patients also have an increased risk of venous thrombosis. The description of end-stage liver...
disease as a state of auto-anticoagulation is misleading. Although there is reduced hepatic synthesis of procoagulant factors, this is balanced to a degree by the reduced production of natural anticoagulant proteins and reduced fibrinolytic activity in patients with advanced liver disease. In severe parenchymal liver disease, bleeding may arise from many different causes. Major bleeding, is often from structural abnormalities such as oesophageal varices or peptic ulcer, and sepsis and volume overload are common precipitants of bleeding. There is reduced hepatic synthesis, for example, of factors V, VII, VIII, IX, X, XI, prothrombin and fibrinogen. Clearance of plasminogen activator is reduced. Thrombocytopenia may occur secondary to hypersplenism in the presence of portal hypertension and due to reduced production and activity of thrombopoietin in advanced liver disease. In cholestatic jaundice, there is reduced vitamin K absorption, leading to deficiency of factors II, VII, IX and X, but also of proteins C and S. Treatment with plasma products or platelet transfusion should be reserved for acute bleeds or to cover interventional procedures such as liver biopsy. Vitamin K deficiency can be readily corrected with parenteral administration of vitamin K.

**Renal failure**

The severity of the haemorrhagic state in renal failure is proportional to the plasma urea concentration. Bleeding manifestations are those of platelet dysfunction, with gastrointestinal haemorrhage being particularly common. The causes are multifactorial and include anaemia, mild thrombocytopenia and the accumulation of low-molecular-weight waste products, normally excreted by the kidney, that inhibit platelet function. Treatment is by dialysis to reduce the urea concentration. Rarely, in severe or persisting bleeding, platelet concentrate infusions and red cell transfusions are indicated. Increasing the concentration of vWF, either by cryoprecipitate or by desmopressin, may promote haemostasis. Patients with significant renal impairment have an increased risk of anticoagulant-related bleeding, particularly with drugs that are at least partially renal excreted.

**Thrombotic disorders**

**Venous thromboembolic disease (venous thromboembolism)**

While the most common presentations of venous thromboembolism (VTE) are deep vein thrombosis (DVT) of the leg (p. 188) and/or pulmonary embolism (PE; see also p. 546), similar management principles apply to rarer manifestations such as jugular vein thrombosis, upper limb DVT, cerebral sinus thrombosis (p. 1186) and intra-abdominal venous thrombosis (e.g. Budd–Chiari syndrome; p. 909).

VTE has an annual incidence of approximately 1:1000 in Western populations. The relative incidence of DVT/PE is approximately 2:1. Mortality 30 days after DVT is approximately 10%, compared to 15% for PE. All forms of VTE are increasingly common with age and many of the deaths are related to coexisting medical conditions, such as active cancer or inflammatory disease, which predispose the patient to thrombosis in the first place. Risk factors for VTE are often present (Box 25.67) and it is appropriate to seek evidence of these risk factors in determining the long-term management strategy. Figure 25.42 illustrates some of the causes and consequences of VTE. The diagnosis of DVT and PE are discussed on pages 188 and 546, respectively.

**Management of VTE**

The mainstay of treatment for all forms of VTE is anticoagulation. This can be achieved in several ways. One option is to use LMWH followed by a coumarin anticoagulant, such as warfarin. Treatment of acute VTE with LMWH should continue for a minimum of 5 days. Patients treated with warfarin should achieve a target INR of 2.5 (range 2–3; pp. 930 and Box 25.25) with LMWH continuing until the INR is above 2. Alternatively, patients may be treated with a DOAC. Rivaroxaban and apixaban may be used immediately from diagnosis without the need for LMWH, while

The licences for dabigatran and edoxaban include initial treatment with LMWH for a minimum of 5 days before commencing the DOAC (see Fig. 25.41). In patients with active cancer and VTE, maintenance anticoagulation with LMWH is associated with a lower recurrence rate than warfarin. The use of DOACs in cancer-associated thrombosis is under study. Small studies suggest a possible role for apixaban and rivaroxaban in this context. Patients who have had VTE and have a strong contraindication to anticoagulation and those who continue to have new pulmonary emboli despite therapeutic anticoagulation should have an inferior vena cava (IVC) filter inserted to prevent life-threatening PE.

The optimal initial period of anticoagulation is between 6 weeks and 6 months. Patients with a provoked VTE in the presence of a temporary risk factor, which is then removed, can usually be treated for short periods (e.g. 3 months), and indeed anticoagulation for more than 6 months does not alter the rate of recurrence following discontinuation of therapy. If there are ongoing risk factors that cannot be alleviated, such as active cancer, long-term anticoagulation is usually recommended, provided that the risk of bleeding is not deemed excessive.

For patients with unprovoked VTE, the optimum duration of anticoagulation can be difficult to establish. Recurrence of VTE is about 2%–3% per annum in patients who have a temporary medical risk factor at presentation and about 7%–10% per annum in those with apparently unprovoked VTE. This plateaus at around 30%–40% recurrence at 5 years. As such, many patients who have had unprovoked episodes of VTE will benefit from long-term anticoagulation. Several factors predict risk of recurrence following an episode of unprovoked VTE. The strongest
predictors of recurrence are male sex and a positive D-dimer assay measured 1 month after stopping anticoagulant therapy. These factors are incorporated into scoring systems to predict recurrence such as the DASH score, HERDOO2 score and the Vienna prediction model.

The management of DVT of the leg should also include elevation and analgesia; in limb-threatening DVT, thrombolysis may also be considered. Thrombolysis for PE is discussed in Chapter 17. Post-thrombotic syndrome is due to damage of venous valves by the thrombus. It occurs in around 30% of patients who sustain a proximal lower limb DVT and results in persistent leg swelling, heaviness and disconnection. The most severe complication of this syndrome is ulceration around the medial malleolus (see Fig. 25.42). Use of elastic compression stockings following a DVT does not reduce the incidence of post-thrombotic syndrome.

Prophylaxis of VTE

All patients admitted to hospital should be assessed for their risk of developing VTE and appropriate prophylactic measures should be put in place. Both medical and surgical patients are at increased risk. A summary of the risk categories is given in Box 25.68. Early mobilisation of patients is important to prevent DVT and those at medium or high risk may require additional antithrombotic measures; these may be pharmacological or mechanical. There is increasing evidence in high-risk groups, such as patients who have had major lower limb orthopaedic surgery and abdominal or pelvic cancer surgery, for protracted thromboprophylaxis for as long as 30 days or so after the procedure. Particular care should be taken with the use of pharmacological prophylaxis in patients with a high risk of bleeding or with specific risks of haemorrhage related to the site of surgery or the use of spinal or epidural anaesthesia.

Inherited and acquired thrombophilia and prothrombotic states

Several inherited conditions predispose to VTE (see Box 25.67), and have several points in common that are worth noting:

- None of them is strongly associated with arterial thrombosis.
- All are associated with a slightly increased incidence of adverse outcome of pregnancy, including recurrent early fetal loss, but there are no data to indicate that any specific intervention changes that outcome.
- Apart from in antithrombin deficiency and homozygous factor V Leiden, most carriers of these genes will never have an episode of VTE; if they do, it will be associated with the presence of an additional temporary risk factor.
- There is little evidence that detection of these abnormalities predicts recurrence of VTE over and above the validated scoring systems mentioned above.
Antithrombotic prophylaxis

Indications
Patients in the following categories should be considered for specific antithrombotic prophylaxis:

Moderate risk of DVT
- Major surgery:
  - In patients >40 years or with other risk factor for VTE
- Major medical illness, e.g.:
  - Heart failure
  - Myocardial infarction with complications
  - Sepsis
  - Inflammatory conditions, including inflammatory bowel disease
  - Active malignancy
  - Nephrotic syndrome
  - Stroke and other conditions leading to lower limb paralysis

High risk of DVT
- Major abdominal or pelvic surgery for malignancy or with history of DVT or known thrombophilia (see Box 25.4)
- Major hip or knee surgery
- Neurosurgery

Methods of VTE prophylaxis

Mechanical
- Intermittent pneumatic compression
- Mechanical foot pumps

Pharmacological
- LMWHs
- Unfractionated heparin
- Fondaparinux
- Dabigatran
- Rivaroxaban
- Apixaban
- Warfarin

(DVT = deep vein thrombosis; VTE = venous thromboembolism)

Antithrombin deficiency
Antithrombin (AT) is a serine protease inhibitor (SERPIN) that inactivates the activated coagulation factors IIa, Xa, X and XIa. Heparins and fondaparinux achieve their therapeutic effect by potentiating the activity of AT. Familial deficiency of AT is inherited in an autosomal dominant manner; homozygosity for mutant alleles is not compatible with life. Around 70% of affected individuals will have an episode of VTE before the age of 60 years and the relative risk for thrombosis compared with the background population is 10–20-fold. Pregnancy is a high-risk period for VTE and this requires fairly aggressive management with doses of LMWH that are greater than the usual prophylactic doses (>100IU/kg/day). AT concentrate (either plasma-derived or recombinant) is available; this is required for cardiopulmonary bypass and may be used as an adjunct to heparin in surgical prophylaxis and in the peripartum period.

Protein C and S deficiencies
Protein C and its co-factor protein S are vitamin K-dependent natural anticoagulants involved in switching off coagulation factor activation (factors Va and VIIIa) and so thrombin generation (see Fig. 25.6F). Inherited deficiency of either protein C or S results in a prothrombotic state with a 5-fold relative risk of VTE compared with the background population.

Factor V Leiden
Factor V Leiden results from a gain-of-function, single-base-pair mutation, which prevents the cleavage and hence inactivation of activated factor V. This results in a relative risk of venous thrombosis of 5 in heterozygotes and 50 or more in rare homozygotes. The mutation is found in about 5% of Northern Europeans, 2% of Africans, 1.2% of African Americans, 0.5% of Asian Americans and 1.25% of Indigenous Americans, and is rare in Chinese and Malay people.

Prothrombin G20210A
This gain-of-function mutation in the non-coding 3' end of the prothrombin gene is associated with an increased plasma level of prothrombin. It is present in about 2% of Northern Europeans, but is rare in native populations of Korea, China, India and Africa. In the heterozygous state, it is associated with a 2–3-fold increase in risk of VTE compared with the background population.

Antiphospholipid syndrome
Antiphospholipid syndrome (APS) is a clinicopathological entity in which a constellation of clinical conditions, alone or in combination, is found in association with a persistently positive test for an antiphospholipid antibody. The antiphospholipid antibodies are heterogeneous and typically are directed against proteins that bind to phospholipids (Box 25.69). Although causal roles for these antibodies have been proposed, the mechanisms underlying the clinical features of APS are not clear. In clinical practice, two types of test are used, which detect:

- Antibodies that bind to negatively charged phospholipid on an ELISA plate (called an anticardiolipin antibody test; these assays usually contain β₂-glycoprotein 1 (β₂-GP1)
- Those that interfere with phospholipid-dependent coagulation tests like the APTT or the dilute Russell viper venom time (DRVT; called a lupus anticoagulant test).

The term antiphospholipid antibody encompasses both a lupus anticoagulant and an anticardiolipin antibody/anti-β₂-GP1; individuals may be positive for one, two or all three of these activities. It has been shown that patients who are ‘triple positive’ have an increased likelihood of thrombotic events compared with single or double positives.

Clinical features and management
APS may present in isolation (primary APS) or in association with one of the conditions shown in Box 25.69, most typically systemic lupus erythematosus (secondary APS). Most patients present with a single manifestation and APS is now most frequently diagnosed in women with

### 25.69 Antiphospholipid syndrome (APS)

#### Clinical manifestations
- Adverse pregnancy outcome
  - Recurrent first trimester abortion (>3)
  - Unexplained death of morphologically normal fetus after 10 weeks' gestation
  - Severe early pre-eclampsia
- Venous thromboembolism
- Arterial thromboembolism
- Livedo reticularis, catastrophic APS, transverse myelitis, skin necrosis, chorea

#### Conditions associated with secondary APS
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Systemic sclerosis
- Behçet’s disease
- Temporal arteritis
- Sjögren syndrome

#### Targets for antiphospholipid antibodies
- β₂-glycoprotein 1
- Protein C
- Annexin V
- Prothrombin (may result in haemorrhagic presentation)
adverse outcomes of pregnancy. It is extremely important to make the diagnosis in patients with APS, whatever the manifestation, because it affects the prognosis and management of arterial thrombosis, VTE and pregnancy.

Arterial thrombosis, typically stroke, associated with APS should probably be treated with anti-coagulation, as opposed to anti-platelet therapy. APS-associated VTE is one of the situations in which the predicted recurrence rate is high enough to indicate long-term anti-coagulation after a first event. Recent evidence suggests that patients with APS presenting with thrombotic events should receive warfarin as opposed to a DOAC as anticoagulant of choice. In women with obstetric presentations of APS, intervention with heparin and aspirin is almost routinely prescribed, although there is little evidence from clinical trials that it is an effective therapy in increasing the chance of a successful pregnancy outcome.

### Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) may complicate a range of illnesses (Box 25.70). It is characterised by systemic activation of the pathways involved in coagulation and its regulation. This may result in the generation of intravascular fibrin clots causing multi-organ failure, with simultaneous coagulation factor and platelet consumption, causing bleeding. The systemic coagulation activation is induced either through cytokine pathways, which are activated as part of a systemic inflammatory response, or by the release of procoagulant substances such as tissue factor. In addition, suboptimal function of the natural anticoagulant pathways and dysregulated fibrinolysis contribute to DIC. There is consumption of platelets, coagulation factors (notably factors V and VIII) and fibrinogen. The lysis of fibrin clot results in production of fibrin degrada tion products (FDPs), including D-dimers.

### Investigations

DIC should be suspected when any of the conditions listed in Box 25.70 are met. Measurement of coagulation times (APTT and PT; see Box 25.3) along with fibrinogen, platelet count and FDPs, helps in the assessment of prognosis and aids clinical decision-making with regard to both bleeding and thrombotic complications.

### Management

Therapy is primarily aimed at the underlying cause. These patients will often require intensive care to deal with concomitant issues, such as acidosis, dehydration, renal failure and hypoxia. Blood component therapy, such as fresh frozen plasma, cryoprecipitate and platelets, should be given if the patient is bleeding or to cover interventions with a high bleeding risk, but should not be prescribed routinely based on coagulation tests and platelet counts alone. Prophylactic doses of heparin should be given, unless there is a clear contraindication. Established thrombosis should be treated cautiously with therapeutic doses of unfractionated heparin, unless clearly contraindicated. Patients with DIC should not, in general, be treated with antifibrinolytic therapy, e.g. tranexamic acid.

### Thrombotic thrombocytopenic purpura

Like DIC and also heparin-induced thrombocytopenia (p. 937), thrombotic thrombocytopenic purpura (TTP) is a disorder in which thrombosis is accompanied by paradoxical thrombocytopenia. TTP is characterised by a pentad of findings, although few patients have all five components:

- thrombocytopenia
- microangiopathic haemolytic anaemia
- neurological sequelae
- fever
- renal impairment.

It is an acute autoimmune disorder mediated by antibodies against ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif).

This enzyme normally cleaves vWF multimers to produce normal functional units, and its deficiency results in large vWF multimers that cross-link platelets. The features are of microvascular occlusion by platelet thrombi affecting key organs, principally brain and kidneys. It is a rare disorder (1 in 750,000 per annum), which may occur alone or in association with drugs (ticlopidine, ciclosporin), HIV, shiga toxins (Ch. 13) and malignancy. It should be treated by emergency plasma exchange. Glucocorticoids, aspirin and rituximab also have a role in management. Caplacizumab, a monoclonal antibody directed against the A domain of vWF, is associated with improved outcomes, less relapse and faster time to recovery in patients with acquired TTP. Untreated mortality rates are 90% in the first 10 days, and even with appropriate therapy, the mortality rate is 20%–30% at 6 months.

**Multiple Choice Questions**

25.1. Which of the following is not true of emicizumab?

A. It emulates the role of factor VIII by allowing formation of the tenase complex
B. It is useful in the management of haemophilia A
C. It is useful in the management of haemophilia A patients with inhibitors
D. It is a bispecific monoclonal antibody
E. It is given intravenously three times weekly to provide prophylaxis

Answer: E.

Emicizumab is a bispecific monoclonal antibody which replicates the action of factor VIII in making the tenase complex. This results in downstream activation of factor X and subsequently thrombin and clot generation. Emicizumab can therefore be used in all categories of haemophilia A and has had its greatest effect on patients with inhibitors. Its great clinical advantage is that it is a subcutaneous preparation.

25.2. A 20-year-old woman who has sustained an apparently unprovoked pulmonary embolism has a positive test for a lupus anticoagulant on admission. Both anticardiolipin and anti-beta2-glycoprotein-1 antibodies are negative. She has no history of SLE or any connective tissue disease. Which of the following best describes the diagnosis and management?

A. She has antiphospholipid syndrome and she should be anticoagulated indefinitely with low molecular weight heparin which is the drug of choice in APS
B. She does not have antiphospholipid syndrome because aCL and anti-B2 GP-1 are both negative
C. She has antiphospholipid syndrome and she should be anticoagulated indefinitely with warfarin which is the drug of choice in APS
D. She may have APS but only if she has a repeated positive LA 12 weeks after the first positive
E. She does not have proven APS and should be anticoagulated indefinitely with rivaroxaban

Answer: D.

APS is a clinicopathological entity comprising a clinical event (thrombosis in arterial or venous circulation or adverse outcome of pregnancy) accompanied by a persistent positive antiphospholipid antibody test (any) on two occasions at least 12 weeks apart. Recent data from the TRAPS study has resulted in the regulatory bodies indicating that warfarin is the optimal anticoagulant for patients with VTE associated with APS.

25.3. A 7-year-old Italian boy attends the local hospital. He has been unwell for 5 days with a mild fever, low energy and poor appetite. On examination he is listless with conjunctival pallor. His cheeks appear flushed. A widespread, fine erythematous rash over the trunk and limbs is noted. Bloods show:

- WBC 14.9 x 10^9/L (4–11)
- Hb 51 g/L (113–141)
- MCV 72 fl (80–100)
- Reticulocytes 12 x 10^9/L (25–85)
- Bilirubin 62 μmol/L (3–21)
- Blood film: many spherocytes and atypical lymphocytes

What is the most likely diagnosis?

A. Hereditary spherocytosis with acute haemolytic crisis
B. Infectious mononucleosis
C. Hereditary spherocytosis with megaloblastic crisis
D. Hereditary elliptocytosis with acute haemolytic crisis
E. Hereditary spherocytosis with aplastic crisis

Answer: D.

Parvovirus B19 (erythrovirus) will precipitate an aplastic crisis in hereditary spherocytosis. There is a characteristic ‘flushed cheeks’ rash. The virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count. An elevated MCV is associated with a megaloblastic crisis and an acute haemolytic crisis where a reticulocytosis will also be prominent. Elliptocytes are found in hereditary elliptocytosis. Infected mononucleosis presents with sore throat, lymphadenopathy and atypical mononuclear cells on the blood film in the absence of spherocytes.

25.4. A 55-year-old man presents with further relapse of diffuse large B-cell non-Hodgkin lymphoma (DLBL) having failed previous treatments with R-CHOP chemotherapy and R-DHAP chemotherapy followed by autologous stem cell transplantation. In considering further treatment with CAR-T-cell therapy which of the following statements is true?

A. The patient must achieve a negative FDG PET-CT prior to CAR-T-cell therapy
B. CAR-T cells can be prepared and delivered within one week
C. The T cells are most commonly provided by an unrelated donor
D. A chimeric antigen receptor (CAR) is composed of part antibody molecule and part T-cell receptor
E. The treatment works by exhausting cytotoxic T-cell function

Answer: D.

The patient fulfils one of the currently licensed indications for CAR-T-cell therapy of multiply relapsed DLBL. The patient does not have to be in remission but the disease needs to be controlled enough for the patient to be fit enough for the procedure. The process of preparing CAR-T cells is complex and takes about 8 weeks in total. Current CAR-T cells use autologous T cells taken from the patient. Future CAR-T cell products may be prepared from donor T cells as so-called ‘off the shelf’ CAR-T cells’. The CAR-T cells work by enhanced recognition and killing of lymphoma cells by the modified T cells. T-cell exhaustion is a process by which tumours protect themselves. Checkpoint inhibitors reverse this process.

25.5. A 40-year-old woman presents with a persistent blocked nose associated with swelling of the left cheek. A CT scan shows a mass in the post-nasal space and involving the left maxillary sinus. A biopsy confirms plasmacytoma. Which of the following is in keeping with a diagnosis of solitary plasmacytoma?

A. Multiple lytic bone lesions on an MRI scan
B. 20% plasma cells in a bone marrow sample taken from the posterior iliac crest
C. Pancytopenia
D. Hypercalcaemia associated with acute renal failure
E. Low-level IgG paraprotein

Answer: E.

Extramedullary solitary plasmacytomas most commonly occur in the upper aero-digestive tract. They present as isolated tumours of plasma cells and other features of disseminated myeloma including multiple lytic lesions, hypercalcaemia, widespread marrow involvement and cytopenias are absent. A low-level intact paraprotein is commonly seen.

   - Alopecia
   - Mouth ulcers
   - Eyes

4. Trunk
   - Kyphosis
   - Scoliosis
   - Tender spots (fibromyalgia, enthesitis)

5. Legs
   - Deformity
   - Swelling
   - Restricted movement

6. Feet
   - Deformity
   - Swelling (gout, dactyliitis)
   - Redness

Observation
- General appearance
- Gait
- Deformity
- Swelling
- Redness
- Rash

- Bone deformity in Paget’s disease
- Acute gout
General Assessment of Locomotor System (GALS) and Schöber's test

1 Gait
Ask patient to walk for a few steps, then come back. Look for pain or limp.

2 Arms
- Inspect hands for swelling or deformity
- Ask patient to make a fist and open and close fingers (tests hand function)
- Squeeze metacarpals (tests for inflammation)
- Press over supraspinatus (tests for hyperalgia)
- Ask patient to put hands behind head (tests shoulder movements)
- Patient turns palms up and down with elbows at side (tests supination and pronation of wrists and elbow)
- Patient flexes elbows to touch shoulder (tests elbow flexion)

3 Legs
- Flex each hip with hand on knee. Rotate hips internally and externally (tests hip movements and detects knee crepitus)
- Palpate each knee for warmth and swelling (tests for synovitis and effusion)
- Inspect ankles and feet. Squeeze forefoot (tests for metatarsophalangeal synovitis)

4 Spine
- Patient looks at ceiling and then puts chin on chest (tests flexion and extension cervical spine)
- Ask patient to try to put ear on shoulder (tests lateral flexion cervical spine)
- Patient slides hand down leg to knee (tests lateral spine flexion)
- Inspect spine from behind and side, looking for scoliosis, kyphosis or localised deformity. Ask patient to touch toes

5 Schöber's test
Mark skin with pen in midline about 4 cm below superior iliac crest. Make another mark in midline 10 cm above first. Ask patient to bend forwards. Normally, distance between marks should increase to 15 cm.

Stand behind patient and hold their pelvis. Ask them to turn from side to side without moving their feet (tests thoracolumbar rotation)
Disorders of the musculoskeletal system affect all ages and ethnic groups. In the UK, about 25% of new consultations in general practice are for musculoskeletal symptoms. Musculoskeletal diseases may arise from processes affecting bones, joints, muscles, or connective tissues such as skin and tendon. The principal manifestations are pain and impairment of locomotor function.

Diseases of the musculoskeletal system tend to be more common in women and most increase in frequency with increasing age. They are the most common cause of physical disability in older people and account for one-third of physical disability at all ages.

**Functional anatomy and physiology**

The musculoskeletal system is responsible for movement of the body, provides a structural framework to protect internal organs and acts as a reservoir for storage of calcium and phosphate in the regulation of mineral homeostasis. The main components of the musculoskeletal system are depicted in Figure 26.1.

**Bone**

Bones fall into two main types, based on their embryonic development. Flat bones, such as the skull, develop by intramembranous ossification, in which embryonic fibroblasts differentiate directly into bone within condensations of mesenchymal tissue during early fetal life. Long bones, such as the femur and radius, develop by endochondral ossification from a cartilage template. During development, the cartilage is invaded by vascular tissue containing osteoprogenitor cells and is gradually replaced by bone from centres of ossification situated in the middle and at the ends of the bone. A thin remnant of cartilage called the growth plate or epiphysis remains at each end of long bones and chondrocyte proliferation here is responsible for skeletal growth during childhood and adolescence. At the end of puberty, the increased levels of sex hormones halt cell division in the growth plate. The cartilage remnant then disappears as the epiphysis fuses and longitudinal bone growth ceases.

Two types of bone tissue are present in the normal skeleton (Fig. 26.1). Cortical bone is formed from Haversian systems, comprising concentric lamellae of bone tissue surrounding a central canal that contains blood vessels. Cortical bone is dense and forms a hard envelope around the long bones. Trabecular or cancellous bone fills the centre of the bone and consists of an interconnected meshwork of trabeculae, separated by spaces filled with bone marrow. Important cell types in bone are:

- **Osteoclasts**: multinucleated cells of haematopoietic origin, responsible for bone resorption.
- **Osteoblasts**: mononuclear cells derived from marrow stromal cells responsible for bone formation.
- **Osteocytes**: cells that differentiate from osteoblasts that become embedded in bone matrix during bone formation. They are responsible for sensing and responding to mechanical stimuli and for coordinating osteoclast and osteoblast activity by producing receptor activator of nuclear factor kappa B ligand (RANKL) and sclerostin (SOST).
- **Bone marrow stromal cells**: cells that produce RANKL and macrophage colony-stimulating factor (M-CSF), which act together to stimulate osteoclast formation, and other cytokines that support haematopoiesis.
- **Bone lining cells**: flattened cells lining the bone surface that differentiate from osteoblasts when bone formation is complete.

---

*Fig. 26.1 Structure of the major musculoskeletal tissues.*
**Bone matrix and mineral**

The most abundant protein of bone is type I collagen, which is formed from two $\alpha_1$ peptide chains and one $\alpha_2$ chain wound together in a triple helix. Type I collagen is proteolytically processed inside the cell before being laid down in the extracellular space, releasing propeptide fragments that can be used as biochemical markers of bone formation. Subsequently, the collagen fibrils become “cross-linked” to one another by pyridinium molecules, a process that enhances bone strength. When bone is broken down by osteoclasts, the cross-links are released into the circulation. These can be measured biochemically and are sometimes used clinically to assess levels of bone resorption. Bone is normally laid down in an orderly fashion, but when bone turnover is high, as in Paget’s disease or severe hyperparathyroidism, it is laid down in a chaotic pattern, giving rise to ‘woven bone’ that is mechanically weak. Bone matrix also contains growth factors, other structural proteins and proteoglycans, thought to be involved in helping bone cells attach to bone matrix and in regulating bone cell activity. The other major component of bone is mineral, comprised of calcium and phosphate crystals deposited between the collagen fibrils in the form of hydroxyapatite $[Ca_{10} (PO_{4})_{6} (OH)]_n$. Mineralisation is essential for bone rigidity and strength, but over-mineralisation causes bone to become brittle. In clinical practice, increased mineralisation can occur in some types of osteogenesis imperfecta and in response to long-term bisphosphonate therapy.

**Bone remodelling**

Bone remodelling is required for renewal and repair of the skeleton throughout life. This is a cyclical process that has four phases: quiescence, resorption, reversal and formation, as illustrated in Figure 26.2. Remodelling starts with the attraction of osteoclast precursors in peripheral blood to the target site, probably by local release of chemotactic factors from areas of microdamage. The osteoclasts resorb bone and, after about 10 days, undergo programmed cell death (apoptosis), heralding the start of the reversal phase when osteoblast precursors are recruited to the resorption site. The osteoblast precursors differentiate into mature osteoblasts and form new bone during the formation phase. Initially, the matrix is unmineralised (osteoid) but eventually becomes mineralised to form mature bone. Some osteoblasts become trapped in bone matrix and differentiate into osteocytes, which play a key regulatory role in coordinating bone formation and resorption, whereas others differentiate into bone-lining cells.

The cellular and molecular mediators of this bone remodelling are shown in more detail in Figure 26.3. Osteoclast precursors are derived from haematopoietic stem cells and differentiate into mature osteoclasts.

---

**Figure 26.2** The bone remodelling cycle. Bone is renewed and repaired by the process of bone remodelling. This begins by removal of old and damaged bone by osteoclasts during the phase of bone resorption. After about 10 days, the osteoclasts undergo programmed cell death (apoptosis) and during the reversal phase are replaced by osteoblasts, which begin to fill in the resorbed area with new bone matrix, heralding the start of bone formation. The bone matrix is initially uncalcified (osteoid) but then becomes mineralised to form mature bone.

**Figure 26.3** Cellular and molecular regulators of bone remodelling. Osteoclast precursors are derived from haematopoietic stem cells. They differentiate into mature osteoclasts in response to the receptor activator of nuclear factor kappa B ligand (RANKL), which is produced by osteocytes, bone marrow stromal cells and activated T cells (not shown), and macrophage colony-stimulating factor (M-CSF), which is produced by bone marrow stromal cells. Osteoprotegerin (OPG) is also produced in the bone microenvironment, where it inhibits osteoclastic bone resorption by blocking the effect of RANKL. Osteoblasts, which are derived from bone marrow stromal cells, are responsible for bone formation. Osteoblast activity is stimulated by signalling molecules in the Wnt family but inhibited by sclerostin (SOST), which is produced by osteocytes. In addition to their role in regulating osteoclast and osteoblast activity, osteocytes have an endocrine function in regulating phosphate homeostasis by producing fibroblast growth factor 23 (FGF23), which acts on the kidney to promote phosphate excretion.
in response to M-CSF, produced by bone marrow stromal cells, and RANKL, produced by both osteocytes and bone marrow stromal cells. The RANKL binds to and activates a receptor called RANK (receptor activator of nuclear factor kappa B) on osteoclast precursors, promoting osteoclast differentiation and bone resorption. This effect is blocked by osteoprotegerin (OPG), which is a decoy receptor for RANKL, that inhibits osteoclast formation. Once formed, mature osteoclasts attach to the bone surface by a tight sealing zone and secrete hydrochloric acid and proteolytic enzymes, including cathepsin K, into the space underneath, which is known as the Howship’s lacuna. The acid dissolves the mineral and cathepsin K degrades collagen. Osteocytes also produce sclerostin (SOST), which is a potent inhibitor of bone formation. Under conditions of mechanical loading, sclerostin production by osteocytes is inhibited, allowing bone formation to proceed, stimulated by members of the Wnt family of signalling proteins. The Wnt molecules stimulate bone formation by activating members of the lipoprotein receptor-related protein (LRP) family, the most important of which are LRP4, LRP5 and LRP6. Sclerostin antagonises the effects of Wnt family members by blocking their interaction with LRP family members. Finally, osteocytes play a critical role in phosphate homeostasis by producing the hormone FGF23, which regulates renal tubular phosphate reabsorption. Key regulators of bone remodelling are summarised in Box 26.1.

Mineralisation of bone is critically dependent on the enzyme alkaline phosphatase (ALP), which is produced by osteoblasts and degrades pyrophosphate, an inhibitor of mineralisation. Bone remodelling is predominantly regulated at a local level but can be influenced by circulating hormones or mechanical loading, which can up-regulate or down-regulate remodelling across the whole skeleton (Box 26.1).

### Joints

There are three main types of joint: fibrous, fibrocartilaginous and synovial (Box 26.2).

#### Fibrous and fibrocartilaginous joints

These comprise a simple bridge of fibrous or fibrocartilaginous tissue joining two bones together where there is little requirement for movement such as the symphysis pubis. The intervertebral disc is a special type of fibrocartilaginous joint in which an amorphous area, called the nucleus pulposus, lies in the centre of the fibrocartilaginous bridge. The nucleus has a high water content and acts as a cushion to improve the disc’s shock-absorbing properties.

#### Synovial joints

These are complex structures containing several cell types. They are found where a wide range of movement is needed (Fig. 26.4).

**Articular cartilage**

This avascular tissue covers the bone ends in synovial joints. Cartilage cells (chondrocytes) are responsible for synthesis and turnover of cartilage, which consists of a mesh of type II collagen fibrils that extend through a hydrated ‘gel’ of proteoglycan molecules. The most important proteoglycan is aggrecan, which consists of a core protein to which several glycosaminoglycan (GAG) side chains are attached (Fig. 26.5). The GAGs are polysaccharides that consist of long chains of disaccharide repeats comprising one normal sugar and an amino sugar. The most abundant GAGs in aggrecan are chondroitin sulphate and keratan sulphate. Hyaluronan is another important GAG that binds to aggrecan molecules to form very large complexes with a total molecular weight of more than 100 million. Aggrecan has a strong negative charge and avidly binds water molecules to assume a shape that occupies the maximum possible volume available. The expansive force of the hydrated aggrecan, combined with the restrictive strength of the collagen mesh, gives articular cartilage excellent shock-absorbing properties.

With ageing, the concentration of chondroitin sulphate decreases, whereas that of keratan sulphate increases, resulting in reduced water content and shock-absorbing properties. These changes differ from those found in osteoarthritis, where there is abnormal chondrocyte division, loss of proteoglycan from matrix and an increase in water content.

**Fig. 26.4** These are complex structures containing several cell types. They are found where a wide range of movement is needed.
Cartilage matrix is constantly turning over and in health there is a perfect balance between synthesis and degradation. Degradation of cartilage matrix is carried out by aggrecanases and matrix metalloproteinases, responsible for the breakdown of proteins and proteoglycans, and by glycosidases, responsible for the breakdown of GAGs. Pro-inflammatory cytokines, such as interleukin (IL)-1 and tumour necrosis factor (TNF), which are released during inflammation, stimulate production of aggrecanase and metalloproteinases, causing cartilage degradation.

**Synovial fluid**

The surfaces of articular cartilage are separated by a space filled with synovial fluid (SF), a viscous liquid that lubricates the joint. It is an ultrafiltrate of plasma, into which synovial cells secrete hyaluronan and proteoglycans.

**Intra-articular discs**

Some joints contain fibrocartilaginous discs within the joint space that act as shock absorbers. The most clinically important are the menisci of the knee. These are avascular structures that remain viable because of diffusion of oxygen and nutrients from the SF.

**Synovial membrane, joint capsule and bursae**

The bones of synovial joints are connected by the joint capsule, a fibrous structure richly supplied with blood vessels, nerves and lymphatics which encases the joint. Ligaments are discrete, regional thickenings of the capsule that act to stabilise joints (see Fig. 26.4). The inner surface of the joint capsule is the synovial membrane, comprising an outer layer of blood vessels and loose connective tissue that is rich in type I collagen, and an inner layer 1–4 cells thick consisting of two main cell types. Type A synoviocytes are phagocytic cells derived from the monocyte/macrophage lineage and are responsible for removing particulate matter from the joint cavity; type B synoviocytes are fibroblast-like cells that secrete SF. Most inflammatory and degenerative joint diseases are associated with thickening of the synovial membrane and infiltration by lymphocytes, polymorphs and macrophages.

Bursae are hollow sacs lined with synovium and contain a small amount of SF. They help tendons and muscles move smoothly in relation to bones and other articular structures.

**Skeletal muscle**

Skeletal muscles are responsible for body movements and respiration. Muscle consists of bundles of cells (myocytes) embedded in fine connective tissue containing nerves and blood vessels. Myocytes are large, elongated, multinucleated cells formed by fusion of mononuclear precursors (myoblasts) in early embryonic life. The nuclei lie peripherally and the centre of the cell contains actin and myosin molecules, which interdigitate with one another to form the myofibrils that are responsible for muscle contraction. The molecular mechanisms of skeletal muscle contraction are the same as for cardiac muscle (p. 389). Myocytes contain many mitochondria that provide the large amounts of adenosine triphosphate (ATP) necessary for muscle contraction and are rich in the protein myoglobin, which acts as a reservoir for oxygen during contraction.

Individual myofibrils are organised into bundles (fasciculi) that are bound together by a thin layer of connective tissue (the perimysium). The surface of the muscle is surrounded by a thicker layer of connective tissue, the epimysium, which merges with the perimysium to form the muscle tendon. Tendons are tough, fibrous structures that attach muscles to a point of insertion on the bone surface called the enthesis. Entheses transmit tensile load from soft tissues to bone and are composed of either fibrous tissue or fibrocartilage, depending on the local needs of the tissue in adapting to physical stress. The entheses are particularly affected by inflammation in patients with spondyloarthritis, as discussed later in this chapter.

**Investigation of musculoskeletal disease**

Clinical history and examination usually provide sufficient information for the diagnosis and management of many musculoskeletal diseases. Investigations are helpful in confirming the diagnosis, assessing disease activity and indicating prognosis. Investigations that are commonly used in musculoskeletal disease are discussed in more detail below.

**Joint aspiration**

Joint aspiration with examination of SF is pivotal in patients with suspected septic arthritis, crystal arthritis or intra-articular bleeding. It should be carried out in all individuals with acute monoarthritis and samples should be sent for microbiology and clinical chemistry.

It is possible to obtain SF by aspiration from most peripheral joints and only a small amount is required for diagnostic purposes. Normal SF is present in small volume, is clear and either colourless or pale yellow, and has a high viscosity. It contains few cells. With joint inflammation, the volume increases, the cell count and the proportion of neutrophils rise (causing turbidity), and the viscosity reduces (due to enzymatic degradation of hyaluronan and aggrecan). Turbid fluid with a high neutrophil count occurs in septic arthritis, crystal arthritis and reactive arthritis. High concentrations of urate crystals or cholesterol can make SF appear white. Non-uniform blood-staining usually reflects needle trauma to the synovium. Uniform blood-staining is most commonly due to a bleeding diathesis, trauma or pigmented villonodular synovitis, but can also occur in severe inflammatory synovitis. A lipid layer floating above blood-stained
Delayed injection also eases over time when structural damage to the joints is suspected.

Because calcinosis and autoimmune connective tissue diseases, calcinosis cartilage, are associated with tendons, fascia, subcutaneous fat, and periarticular tissues, and may be observed in spondyloarthropathy (SpA; see Fig. 26.41). Erosions, associated with new bone formation and periosteal reaction, also occur in peripheral joints and at entheses in SpA. In tophaceous gout, well-defined punched-out erosions may occur (see Fig. 26.27). Calcification of cartilage, tendons and soft tissues or muscle occurs mainly in chondrocalcinosis (see Fig. 26.29), calcium-containing crystal diseases, tumoral calcinosis and autoimmune connective tissue diseases.

X-rays are of limited value in the diagnosis of rheumatoid arthritis (RA) because features such as erosions, joint space narrowing and periarticular osteoporosis may be detectable only after several months or even years. The main indication for X-rays in RA is in the assessment of disease over time when structural damage to the joints is suspected.

Radionuclide bone scintigraphy

Radionuclide bone scintigraphy is mainly used in the diagnosis of metastatic bone disease and Paget’s disease of bone. Abnormalities may also be observed in primary bone tumours, complex regional pain syndrome, OA and different types of inflammatory arthritis, but the changes are non-specific and other imaging modalities are more commonly used. Bone scintigraphy involves gamma-camera imaging following an intravenous injection of ⁹⁹mTc-labelled biphosphonate. Early post-injection images reflect blood flow and can show increased perfusion of inflamed synovium, Pagetic bone or primary or secondary bone tumours. Delayed images taken a few hours later reflect bone remodelling as the

**Imaging**

**Plain X-rays**

X-rays show structural changes that are of value in the differential diagnosis and monitoring of many bone and joint diseases (Box 26.3).

They are of diagnostic value in osteoarthritis (OA), where they demonstrate joint space narrowing that tends to be focal rather than widespread (as seen in inflammatory arthritis). Other features of OA detected on X-rays include osteophytes, subchondral sclerosis, bone cysts and calcified loose bodies within the synovium (see Fig. 26.19). Erosions and sclerosis of the sacroiliac joints and syndesmophytes in the spine may be observed in spondyloarthropathy (SpA; see Fig. 26.41). Erosions, associated with new bone formation and periosteal reaction, also occur in peripheral joints and at entheses in SpA. In tophaceous gout, well-defined punched-out erosions may occur (see Fig. 26.27). Calcification of cartilage, tendons and soft tissues or muscle occurs mainly in chondrocalcinosis (see Fig. 26.29), calcium-containing crystal diseases, tumoral calcinosis and autoimmune connective tissue diseases.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) gives detailed information on anatomy, allowing three-dimensional visualisation of bone and soft tissues that cannot be adequately assessed by plain X-rays. The technique is valuable in the assessment and diagnosis of many musculoskeletal diseases (Box 26.4). T₁-weighted sequences are useful for defining anatomy, whereas T₂-weighted sequences are useful for assessing tissue water content, which is often increased in synovitis and other inflammatory disorders (Fig. 26.7). MRI sequences that suppress signal from fat, such as short T₁ inversion recovery (STIR), are helpful when evaluating inflammatory disease. Contrast agents, such as gadolinium, can be administered to increase sensitivity in detecting erosions and synovitis.

**Ultrasoundography**

Ultrasoundography is a useful investigation for confirmation of small joint synovitis and erosions, for anatomical location of periarticular lesions, for characterisation of tendon lesions and for guided injection of joints and bursae. Ultrasoundography is more sensitive than clinical examination for the detection of early synovitis and can be helpful in the diagnosis and assessment of patients with suspected inflammatory arthritis. In addition to locating synovial thickening and effusions, ultrasound can detect...
increased blood flow within synovium using power Doppler imaging, an option that is available on most modern ultrasound machines (Fig. 26.8). Ultrasound is also used in the differential diagnosis of giant cell arteritis (GCA) to look for evidence of thickening of the vessel wall in the temporal or axillary arteries.

**Computed tomography**

Computed tomography (CT) is used selectively for assessing patients with bone and joint disease. CT may be used when skeletal anatomy needs defining, when calcific lesions are being assessed, when MRI is contraindicated, or when articular regions are being evaluated in which an adjacent joint replacement creates signal artefacts on MRI (using specific metal artefact reduction algorithms).

**Dual X-ray absorptiometry**

Dual X-ray absorptiometry (DXA) is used to measure bone mineral density (BMD) and has a key role in the diagnosis and management of osteoporosis. Measurements at lumbar spine, hip and sometimes forearm are obtained. DXA works on the principle that calcium in bone attenuates passage of X-rays through the tissue in proportion to the amount of mineral present: the more bone mineral present, the higher the BMD value. The results are presented in terms of BMD (in grams of hydroxyapatite per cm²) and as the T-score, which reflect the number of standard deviations by which the patient’s BMD value differs from that in a young healthy control (Fig. 26.9). Osteoporosis is defined to be present when the T-score is −2.5 or below; osteopenia is defined to be present when the T-score lies between −1.0 and −2.5; and normal BMD is defined to be present when the T-score lies between −1.0 and below +2.5. T score values above +2.5 indicate high bone density. It is important to recognize that T-score values fall with age in the whole population as bone density falls, meaning that many people aged 60 and above have osteopenia or osteoporosis based on T-score, even though the BMD results are in the ‘normal range’ for that age group. Bone density needs to be interpreted carefully taking into account coexisting conditions, such as aortic calcification, vertebral fractures, degenerative disc disease and OA, all of which can cause high BMD results even in the presence of osteoporosis. Radiographic correlation is helpful in these circumstances.

**Blood tests**

**Haematology**

Abnormalities in the full blood count (FBC) often occur in inflammatory rheumatic diseases, but changes are usually non-specific. Examples include neutrophilia in crystal arthropides and septic arthritis neutropenia in systemic lupus erythematosus (SLE) and lymphopenia in autoimmune rheumatic and connective tissue diseases. Reduced levels of
haemoglobin and raised platelets are a common and important finding in active inflammatory diseases. Some disease-modifying anti-rheumatic drugs (DMARDs) and biologics can cause marrow toxicity and require regular monitoring of the FBC. Additional tests that are useful in assessing rheumatic diseases include the direct antiglobulin test (which can indicate intravascular haemolysis in SLE).

### Biochemistry

Routine biochemistry is useful for assessing metabolic bone disease, muscle diseases and gout, and is essential in monitoring DMARDs and biologic drugs (renal and hepatic function). Several bone diseases, including Paget’s disease, renal bone disease and osteomalacia, give a characteristic pattern that can be helpful diagnostically (Box 26.5). Serum levels of uric acid are usually raised in gout, but a normal level does not exclude it, especially during an acute attack when uric acid levels temporarily fall. Equally, an elevated serum uric acid does not confirm the diagnosis, since most hyperuricaemic people never develop gout. Levels of C-reactive protein (CRP) are a useful marker of infection and inflammation, and are more specific than the erythrocyte sedimentation rate (ESR). An exception is in autoimmune connective tissue diseases, such as SLE and systemic sclerosis, where CRP may be normal but the ESR raised in active disease. Accordingly, an elevated CRP in a patient with SLE or systemic sclerosis suggests an intercurrent illness, such as sepsis, rather than active disease. Serum creatine phosphokinase (CPK) levels are useful in the diagnosis of myopathy or myositis, but specificity and sensitivity are poor and raised levels may occur in other conditions (Box 26.6).

### Immunology

Autoantibody tests are widely used in the diagnosis of rheumatic diseases. Whatever test is used, the results must be interpreted in light of the clinical picture and the different detection and assay systems used in different hospitals.

#### Rheumatoid factor

Rheumatoid factor (RF) is an antibody directed against the Fc fragment of human immunoglobulin. In routine clinical practice, immunoglobulin M (IgM) RF is usually measured. About 70% of patients with RA test positive for RF, but the specificity for RA is poor (Box 26.7). High RF titres in RA are associated with more severe disease and extra-articular features.

### Anti-citrullinated peptide antibodies

Anti-citrullinated peptide antibodies (ACPA) recognise peptides in which the amino acid arginine has been converted to citrulline by peptidylarginine deiminase, an enzyme abundant in inflamed synovium and in a variety of mucosal structures. Like RF, ACPA is positive in around 70% of people with RA, but specificity is higher (>95%) and consequently ACPA has largely superseded RF in the diagnosis of RA. Like RF, ACPA positivity is associated with more severe disease and extra-articular features. It is important to emphasise that ACPA positivity does not equate to a diagnosis of RA since a proportion of people in the normal population are ACPA positive. These individuals are at increased risk of developing RA at some point in life, but may never do so. The pathogenic role of ACPAs is still debated but they may amplify the synovial response to an inflammatory stimulus.

### Antinuclear antibodies

Antinuclear antibodies (ANAs) are directed against one or more components of the cell nucleus, including nucleic acids and the proteins that process DNA or RNA. They occur in many inflammatory rheumatic diseases, but are also found at low titre in normal individuals and in other diseases (Box 26.8). ANAs are not associated with disease severity or activity. The most common indication for ANA testing is in patients suspected of having SLE or other autoimmune connective tissue diseases. ANA has high sensitivity for SLE (100%), but low specificity (10%–40%). A negative ANA virtually excludes SLE but a positive result does not confirm it.
Anti-DNA antibodies bind to double-stranded DNA (dsDNA). They are useful in SLE monitoring as high titres are associated with more severe disease and an increase in antibody titre may precede relapse. Most commonly, testing for anti-DNA antibodies is performed by enzyme-linked immunosorbent assay (ELISA) but immunofluorescent staining of DNA from the microorganism *Crithidia luciliae* is also used and has a much higher specificity than dsDNA ELISA for the diagnosis of SLE. It is primarily used in patients where the clinical suspicion of SLE is high but where standard dsDNA tests have yielded equivocal results.

It is also possible to screen for antibodies to various extractable nuclear antigens (ENA). These act as biomarkers for certain subtypes of autoimmune connective tissue diseases and some complications of SLE, but for most disorders their sensitivity and specificity are poor (Box 26.9).

**Antiphospholipid antibodies**

These antibodies can be detected in patients with SLE and in the antiphospholipid syndrome (see Box 25.6). In clinical practice, the most commonly used tests are for antibodies to cardiolipin/β2-glycoprotein 1 (β2-GP1) and the dilute Russell viper venom test, which is a functional assay for antibodies that interfere with the clotting mechanism in vitro.

**Antineutrophil cytoplasmatic antibodies**

Antineutrophil cytoplasmatic antibodies (ANCA) are IgG antibodies directed against the cytoplasmatic constituents of neutrophils and are useful in the diagnosis and monitoring of systemic vasculitis. Two common patterns are described by immunofluorescence: cytoplasmatic fluorescence (c-ANCA), which is caused by antibodies to proteinase-3 (PR3); and perinuclear fluorescence (p-ANCA), which is caused by antibodies to myeloperoxidase (MPO) and other proteins, such as lactoferrin and elastase. These antibodies are not specific for vasculitis and positive results may be found in autoimmune liver disease, malignancy, infection (bacterial and human immunodeficiency virus, HIV), inflammatory bowel disease (IBD), RA, SLE and pulmonary fibrosis.

**Complement and complement component antibodies**

Low complement C3 is an indicator of active SLE and some forms of vasculitis owing to consumption of complement by immune complexes (see Fig. 4.4). Low C4 is less specific for SLE activity. High C3 and functional measures of complement activation are non-specific features of inflammation. It is possible to screen for autoantibodies directed against a variety of other complement components. Some have clinical utility. For example, anti-C1q antibodies are associated with SLE, but also occur in hypocomplementemic urticarial vasculitis syndrome (HUUVS).

**Approach to autoantibody testing and interpretation**

Testing for autoantibodies should only be performed to gain support for the diagnosis when clinical assessment suggests there may be an underlying autoimmune disease. They are not screening tests for the presence of autoimmune disease since they have limited sensitivity and specificity (see Box 26.9). Routine re-testing of autoantibody profiles is seldom helpful unless the clinical features of the disease change or evolve with time.

**Tissue biopsy**

Tissue biopsy is useful in confirming the diagnosis in certain musculoskeletal diseases. Synovial biopsy can be useful in selected patients with chronic inflammatory monoarthritis or tenosynovitis to rule out chronic infectious causes, especially mycobacterial infections. Synovial biopsy can be obtained arthroscopically or by using ultrasound guidance under local anaesthetic.

Temporal artery biopsy can be of value in patients suspected of having giant cell arteritis.

Biopsies of affected tissues, such as skin, lung, nasopharynx, gut, kidney and muscle, are of value in confirming a diagnosis of systemic vasculitis.

Muscle biopsy is important in the investigation of myopathy and inflammatory myositis. It is usually taken from the quadriceps or deltoid through a small skin incision under local anaesthetic. Since myositis can be patchy in nature, MRI is sometimes used to localise the best site for biopsy. Immunohistochemical staining, together with plain histology, gives information on primary and secondary muscle and neuromuscular
disease. Repeat biopsies are sometimes used to monitor the response to treatment.

Bone biopsy is occasionally required in patients with infiltrative disorders of bone, renal bone disease, suspected chronic infection or malignancy and rarely to confirm or exclude the presence of osteomalacia. For focal lesions, the biopsy should be taken under X-ray guidance or at open surgery, from an affected site. If a systemic bone disease or disorder of mineralisation is suspected, biopsies are usually taken from the iliac crest using a large-diameter (8 mm) trephine needle under local anaesthetic and processed without demineralisation.

**Electromyography**

Electromyography is of value in the investigation of suspected myopathy and inflammatory myositis, when it shows the diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganised outline
- repetitive bouts of high-voltage oscillations on needle contact with diseased muscle.

**Presenting problems in musculoskeletal disease**

The pattern of joint involvement and time-course can often provide valuable clues to the underlying diagnosis. The most common clinical presentations of musculoskeletal disease are discussed in this section.

**Monoarthritis**

This refers to pain and swelling affecting a single joint. The most common causes are crystal arthritis, sepsis, reactive arthritis and oligoarticular juvenile idiopathic arthritis. Other potential causes are shown in Box 26.10.

**Clinical assessment**

The clinical history, pattern of joint involvement, speed of onset, and age and gender of the patient all give clues to the most likely diagnosis. A very rapid onset (6–12 hours) is suggestive of either gout or acute calcium pyrophosphate arthritis (CPPA), which is also known as pseudogout. Both may be triggered by an intercurrent illness, dehydration or surgery. Gout classically affects younger men and particularly targets the first metatarsophalangeal (MTP) joint, whereas CPPA tends to affect older women, often with pre-existing OA or calcium pyrophosphate deposition (CPPD) disease. Reactive arthritis can also develop acutely and may be preceded by a diarhoeal illness or genital infection. Septic arthritis develops more slowly and continues to progress until treated. Haemarthrosis usually follows an injury and may be associated with a large effusion, in the absence of periarticular swelling or skin change. Pigmented villonodular synovitis also presents with synovial swelling and a large effusion, affecting a single joint but with a gradual onset. Rheumatoid arthritis seldom presents with monoarthritis, but psoriatic arthritis (PsA) can present this way, although the onset is usually more gradual in both conditions. Osteoarthritis can present with pain affecting a single joint, but the onset is gradual. Although there may be bony swelling of joints affected by OA, synovitis and effusions are uncommon.

**Investigations**

Aspiration of the affected joint is mandatory in patients with sudden onset of a hot swollen joint. The fluid should be sent for culture and Gram stain to seek the presence of organisms and should be checked by polarised light microscopy for crystals. Blood cultures should also be taken in patients suspected of having septic arthritis. CRP and ESR should be measured. While values are raised with both infection and inflammation, serial measurements can be useful in assessing the response to treatment. Serum uric acid measurements are of limited value since urate is a negative acute phase reactant and values can fail to within the normal range in acute gout. If investigations suggest CPPA, an elevated serum calcium may suggest underlying primary hyperparathyroidism.

**Management**

If there is any suspicion of septic arthritis, intravenous antibiotics should be given promptly, pending the results of cultures (see Box 26.50). Patients with suspected crystal-induced arthritis or reactive arthritis may be given intra-articular glucocorticoid injections to help the pain and swelling, but only if Gram stain is negative and synovial fluid culture has been negative for 48 hours. Longer-term management should be directed towards the underlying cause.

**Polyarthritis**

This term is used to describe pain and swelling affecting five or more joints or joint groups. The possible causes are listed in Box 26.11 and extra-articular features are listed in Box 26.12.

**Clinical assessment**

The hallmarks of an inflammatory polyarthritis are early-morning stiffness and worsening of symptoms with inactivity, along with synovial swelling and tenderness on examination.

The pattern of involvement can be helpful in reaching a diagnosis (Fig. 26.10). In RA there is typically symmetrical involvement targeting the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and wrists as well as the ankles and metatarsophalangeal (MTP) and PIP joints of the feet. Other large joints may also be affected. In psoriatic arthritis (PsA), thePIP and distal interphalangeal (DIP) joints of the hands are usually affected, often in an asymmetrical pattern and accompanied by nail pitting or early onycholysis. Large joints may also be affected, and psoriasis may or may not be present. In SLE there may be a polyarthritis, but this more usually causes polyarthralgia and tenosynovitis, mainly of distal limb joints and tendons. OA has a similar pattern of involvement to PsA in the hands, but can usually be distinguished by the presence of Heberden’s and Bouchard’s nodes and lack of synovitis and other features of PsA.

**Investigations**

Blood samples should be taken for routine haematology, biochemistry, ESR, CRP, viral serology and an immunological screen, including ANA and ACPA (or RF). If there is clinical suspicion of an inflammatory arthritis, but clinical signs of synovitis are absent, ultrasound examination or MRI may be helpful in confirming the diagnosis.

**Management**

Management should be tailored to the underlying diagnosis. While investigations are in progress non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics may be considered for symptom control. While
glucocorticoids can be helpful in treating symptoms of inflammatory arthritis they should generally be avoided until a definitive diagnosis has been made.

Fracture

Fractures are a common presenting symptom of osteoporosis, but they also occur in other bone diseases, in osteopenia and in some people with a normal skeleton where there has been a high trauma injury.

Clinical assessment

The presentation is with localised bone pain, which is worsened by movement of the affected limb or region. There is usually a history of trauma, but spontaneous fractures can occur in the absence of trauma in severe osteoporosis. Fractures can be divided into several subtypes, based on the precipitating event and presence or absence of an underlying disease (Box 26.13). The main differential diagnosis is soft tissue injury, but fracture should be suspected when there is marked pain and swelling, abnormal movement of the affected limb, crepitus or deformity. Femoral neck fractures typically produce a shortened, externally rotated leg that is painful to move. The pain from vertebral fracture is variable and a high index of suspicion is key to making the diagnosis by imaging, as discussed below.

Investigations

X-rays of the affected site should be taken in at least two planes and examined for discontinuity of the cortical outline (Box 26.14). In addition to demonstrating the fracture, X-rays may also show evidence of an underlying disorder, such as osteoporosis, Paget's disease or osteomalacia. If the X-ray fails to show evidence of a fracture, but clinical suspicion remains high, MRI should be obtained. In many countries patients with low trauma fractures above the age of 50 are referred for a DXA scan to screen for osteoporosis. DXA is also indicated in those under 50 with very strong clinical risk factors for osteoporosis.

Management

Management of fracture in the acute stage requires adequate pain relief, with opiates if necessary, reduction of the fracture to restore normal anatomy and immobilisation of the affected limb to promote healing. This can be achieved either by the use of an external cast or splint, or by internal fixation. Femoral neck fractures present a special management problem since non-union and osteonecrosis are common. This is especially true with intracapsular hip fractures, which should be treated by joint replacement surgery. Following the fracture, rehabilitation is required with physiotherapy and a supervised exercise programme. If the DXA scan shows evidence of osteoporosis or other metabolic bone disease, this should be treated appropriately as described later in this chapter.

Generalised musculoskeletal pain

Clinical assessment

There are a variety of causes of generalised pain, as summarised in Box 26.15. Relentlessly progressive pain occurring in association with weight loss suggests malignant disease with bone metastases. Generalised bone pain may also arise in osteomalacia, primary
is extensive enthesitis. Accompanying generalised pain may also occur in association with Ehrlich–Danlos syndrome hypermobility subtype (hEDS). Pain is a prominent feature in patients with polymyalgia rheumatica and GCA, but this tends to be localised to the pelvic and shoulder girdle. Similarly, pain is also a common feature of inflammatory arthritis and OA but tends to be localised to affected joints. Widespread pain can occur in PsA if there is extensive enthesitis.

**Investigations**

Bone scintigraphy is of value in patients with suspected bone metastases or Paget's disease and can also reveal evidence of stress fractures in osteomalacia. FBC, ESR and CRP may be abnormal in the presence of inflammatory disease and myeloma. Plasma and urine protein electrophoresis should be performed to screen for myeloma, and if abnormalities are detected further imaging should be considered with X-ray, low-dose CT or MRI. Routine biochemistry, vitamin D and parathyroid hormone (PTH) should be measured if osteomalacia is suspected. In Paget's disease, the typical picture is of an elevation in ALP with otherwise normal biochemistry. Investigations are unremarkable in patients with FM and hEDS.

**Management**

Management should be directed towards the underlying cause. Chronic pain of unknown cause and that associated with FM respond poorly to analgesics and NSAIDs, but may respond partially to antineuropathic agents, such as amitriptyline, duloxetine, gabapentin and pregabalalin.

**Muscle weakness**

Muscle weakness can arise from a variety of causes, as shown in Box 26.16. It is important to distinguish between a subjective feeling of generalised weakness occurring with fatigue, and an objective weakness with loss of muscle power and function. The former is a non-specific manifestation of many systemic conditions.
Clinical assessment

Clinical examination should document the presence, pattern and severity of muscle weakness assessed using the Medical Research Council (MRC) scale (no power (0) to full power (5)). Proximal muscle weakness suggests the presence of a myopathy or myositis, which typically causes difficulty in standing from a seated position, walking up steps, squatting and lifting overhead. Worsening of symptoms on exercise and post-exertional cramps suggest a metabolic myopathy, such as glycogen storage disease. A strong family history and onset in childhood or early adulthood suggest muscular dystrophy. Alcohol excess can cause an inflammatory myositis and atrophy of type 2 muscle fibres. Proximal myopathy may be a complication of Cushings syndrome, glucocorticoid therapy and osteomalacia. Myopathy and myositis can also occur in association with many drugs (see Box 26.79) and viral infections, including HIV; in the latter case, it may be due to HIV itself or to treatment with zidovudine. Polymyositis and dermatomyositis in adults are frequently associated with an occult malignancy, emphasising the importance of a thorough general examination of patients with this presentation.

Investigations

Investigations should include routine biochemistry and haematology, ESR, CRP, creatine kinase, serum 25(OH)-vitamin D, PTH, parvovirus, hepatitis B/C, HIV and streptococcus serology, serum and urine protein electrophoresis, serum ACE, ANAs/ENAs, RF, complement and myositis-specific autoantibodies such as Jo-1. Open muscle biopsy (site-directed by MRI detection of abnormal muscle) and electromyography (EMG) are usually required to make the diagnosis. Genetic testing may be of value in patients where an inherited disorder is suspected. Patients suspected to have myositis should be screened for malignancy. Initially this involves a CT scan of the chest, abdomen and pelvis followed by upper gastrointestinal endoscopy and colonoscopy if necessary.

Management

Management is determined by the underlying cause, but all patients with muscle disease should be referred for physiotherapy and graded exercises to maximise muscle function while specific treatment is introduced.

Regional musculoskeletal pain

Regional musculoskeletal pain is a common presenting complaint, usually occurring as the result of age-related degenerative disease of tendons and ligaments, OA and trauma.

Back pain

Back pain is a common symptom that affects 60%–80% of people at some time in their lives. Although the prevalence has not increased, reported disability from back pain has risen significantly in the last 30 years. In Western countries, back pain is the most common cause of sickness-related work absence. In the UK, 7% of adults consult their GP each year with back pain. Globally, low back pain is thought to affect about 9% of the population. The most important causes of low back pain are summarised in Box 26.17.
PsA has a gradual onset and almost always occurs before the age of 40. It is associated with morning stiffness and improves with movement. Spondylolisthesis may cause back pain that is typically aggravated by standing and walking. Occasionally, diffuse idiopathic skeletal hyperostosis (DISH) can cause back pain, but this is not a prominent feature. Arachnoiditis is a rare cause of chronic severe low back pain. It is caused by chronic inflammation of the nerve root sheaths in the spinal canal and can complicate meningitis, spinal surgery or myelography with oil-based contrast agents.

**Investigations**

Investigations are not required in patients with acute mechanical back pain. Those with persistent pain (> 6 weeks) or red flags (see Box 26.19) should undergo further investigation. MRI is the investigation of choice because it can demonstrate spinal stenosis, cord compression or nerve root compression, as well as inflammatory changes in axSpA, malignancy and sepsis. Plain X-rays can be of value in patients suspected of having vertebral compression fractures, OA and degenerative disc disease. If metastatic disease is suspected, bone scintigraphy or CT should be considered. Additional investigations that may be required include routine biochemistry and haematology, ESR and CRP (to screen for infection and inflammatory disease), protein and urine electrophoresis (for myeloma), human leucocyte antigen (HLA)-B27 for axSpA and prostate-specific antigen for prostate carcinoma.

**Management**

Education is important in patients with mechanical back pain. It should emphasise the self-limiting nature of the condition and the fact that exercise is helpful rather than damaging. Regular analgesia and/or NSAIDs may be required to improve mobility and facilitate exercise. Return to
work and normal activity should take place as soon as possible. Bed rest is not helpful and may increase the risk of chronic disability. Referral for physiotherapy should be considered if a return to normal activities has not been achieved by 6 weeks. Low-dose tricyclic antidepressant drugs may help pain, sleep and mood.

Other treatment modalities that are occasionally used include epidural and facet joint injection, traction and lumbar supports, though there is limited randomised controlled trial evidence to support their use. Malignant disease, osteoporosis, Paget’s disease and SpAs require specific treatment of the underlying condition.

Surgery is required in less than 1% of patients with low back pain, but may be needed in progressive spinal stenosis, in spinal cord compression and in some patients with nerve root compression.

### Neck pain

Neck pain is a common symptom that can occur following an injury or falling asleep in an awkward position, as a result of stress or in association with OA of the spine. The causes are shown in Box 26.21. Most cases resolve spontaneously or with a short course of NSAIDs or analgesics and some exercise therapy. Patients with persistent pain that follows a nerve root distribution and those with upper or lower limb neurological signs should be investigated by MRI and, if necessary, referred for a neurosurgical opinion.

### Shoulder pain

Shoulder pain is a common complaint over the age of 40 (Box 26.22). Varying pain patterns associated with common lesions are shown in Figure 26.12. For most shoulder lesions, general management is with analgesics, NSAIDs, local glucocorticoid injections and physiotherapy aimed at restoring normal movement and function. Surgery may be required in patients who have debilitating or persistent symptoms in association with rotator cuff lesions or severe acromioclavicular joint arthritis. If there is subacromial impingement, without evidence of a rotator cuff tear on MRI, subacromial glucocorticoid injection and physiotherapy constitute a reasonable first step. Calcific supraspinatus tendinitis unresponsive to glucocorticoid injection can be treated with barbotage (needle disruption of deposit under ultrasound guidance).

### Elbow pain

The most common causes are repetitive trauma causing lateral epicondylitis (tennis elbow) and medial epicondylitis (golfer’s elbow) (Box 26.23). SpAs, including psoriatic disease, can present with the same symptoms (tendon insertion enthesitis). Management is by rest, analgesics and topical or systemic NSAIDs. Local glucocorticoid injections may be required in resistant cases. Olecranon bursitis can also follow local repetitive trauma, but other causes include infections and gout.

### Hand and wrist pain

Pain from hand or wrist joints is well localised to the affected joint, except for pain from the first carpometacarpal (CMC) joint, commonly targeted by OA or PsA: although maximal at the thumb base, the pain often radiates down the thumb and to the radial aspect of the wrist. Non-articular causes of hand pain include:

### Principles of management

The management of rheumatological disorders should be tailored to the underlying diagnosis. Certain aspects are common to many disorders, however, and the general principles are discussed here. The therapeutic aims are:

- to educate patients about their disease so as to enhance self-management
- to control pain, if it is present
- to optimise function
- to modify the disease process where this is possible
- to identify and treat comorbidity.

These aims are interrelated and success in one area often benefits others. Successful management requires careful assessment of the person as a whole. The management plan should be individualised and patient-centred, should involve relevant members of the multidisciplinary team, and should be agreed and understood by both the patient and all the practitioners that are involved. It must also take into account:

- the patient’s activity requirements and occupational and recreational aspirations
- risk factors that may influence the disease
- the patient’s perceptions and knowledge of the condition
- medications and coping strategies that have already been tried
- comorbid disease and its therapy
- the availability, costs and logistics of appropriate evidence-based interventions.

Generally, the simplest and safest interventions should be tried first. Symptoms and signs may change with time, so the management plan for most patients requires regular review and re-adjustment.

Core interventions that should be considered for everyone with a painful musculoskeletal condition are listed in Box 26.26. There are also other non-pharmacological and drug options, the choice of which depends on the nature and severity of the diagnosis.

### Education and lifestyle interventions

#### Education

Patients must always be informed about the nature of their condition and its investigation, treatment and prognosis, since education can improve outcome. Information and therapist contact can reduce pain and disability, improve self-efficacy and reduce the health-care costs of many musculoskeletal conditions, including OA and RA. The mechanisms are unclear, but in part may result from improved adherence. Benefits are modest, but potentially long-lasting, safe and cost-effective. Education can be provided through one-to-one discussion, written literature, patient-led group education classes and interactive computer programs. Inclusion of the patient’s partner or carer is often appropriate;
this is essential for childhood conditions but also helps in many chronic adult conditions.
For children and adolescents with chronic diseases such as JIA, education and support of the whole family, schooling and psychological support is essential and best delivered through a multidisciplinary team. Patient-run charitable organisations provide a wealth of information and support to patients (see ‘Further information’). The detail of the educational materials and services that organisations can provide should be known to the multidisciplinary team and organisation contact details should be made available to patients.

**Exercise**

Several types of exercise can be prescribed:

- **Aerobic fitness training** can produce long-term reduction in pain and disability. It improves well-being, encourages restorative sleep and benefits common comorbidity, such as obesity, diabetes, chronic heart failure and hypertension.
- **Local strengthening** exercise for muscles that act over compromised joints also reduces pain and disability, with improvements in the reduced muscle strength, proprioception, coordination and balance that associate with chronic arthritis. ‘Small amounts often’ of strengthening exercise are better than protracted sessions performed infrequently.
- **Weight-bearing exercise** is of value in osteoporosis, where it can result in modest increases in bone density and slow bone loss.

**Joint protection**

Excessive impact-loading and adverse repetitive use of a compromised joint or periarticular tissue can worsen symptoms in patients with arthritis. This can be mitigated by cessation of contact sports and by pacing of activities by dividing physical tasks into shorter segments with brief breaks in between. Other strategies include adaptations to machinery or tools at the workplace; the use of shock-absorbing footwear with thick soft soles, which can reduce impact-loading through feet, knees, hips and back; and the use of a walking stick on the contralateral side to a painful hip, knee or foot.

**Non-pharmacological interventions**

**Physical and occupational therapy**

Local heat, ice packs, wax baths and other local external applications can induce muscle relaxation and provide temporary relief of symptoms in a range of rheumatic diseases.

Hydrotherapy and balneotherapy (immersion in a bath) induce muscle relaxation and facilitate movement in a warm, pain-relieving environment without the restraints of gravity and normal load-bearing. Various manipulative techniques may also help improve restricted movement.

Splints can give temporary rest and support for painful joints and periarticular tissues, and can prevent harmful involuntary postures during sleep. Prolonged rest must be avoided. Orthoses are more permanent appliances used to reduce instability and excessive abnormal movement and provide support and comfort. They include working wrist splints, knee braces, iron and T-straps to control ankle instability and a multitude of (often custom-made) foot insole supports to offload painful or deformed foot structures. Orthoses are particularly suited to severely disabled patients in whom a surgical option is inappropriate and often need to be custom-made for the individual.

Aids and appliances can provide dignity and independence for patients with respect to activities of daily living. Common examples are a raised toilet seat, raised chair height, extended handles on taps, a shower instead of a bath, thick-handled cutlery and extended ‘hands’ to pull on tights and socks. Full assessment and advice from an occupational therapist maximise the benefits of these aids.

**Self-help and coping strategies**

These plans help patients to cope better with, and adjust to, chronic pain and disability. They may be useful at any stage but are particularly beneficial for patients with incurable problems who have tried all accessible treatment options. The aim is to increase self-management through self-assessment and problem-solving, so that patients can recognise negative, but potentially remediable, aspects of their mood (stress, frustration, anger or low self-esteem) and their situation (physical, social, financial). These may then be addressed by changes in attitude and behaviour, as shown in Box 26.27.

Involvement of the spouse or partner in mutual goal-setting can improve partnership adjustment. Such approaches are often an element of group education classes and pain clinics, but may require more formal clinical psychological input.

Tailored multidisciplinary approaches are required for patients with juvenile idiopathic arthritis (JIA) and other chronic childhood diseases, dependent on age and maturity. Adolescents and young adults have specific demands, different to those of young children and adults, which are influenced by many issues in their lives implying on the disease process, its impact and their ability to cope with it.

**Weight control**

Obesity aggravates pain at most sites through increased mechanical strain and is a risk factor for progression of joint damage in patients with OA and other types of arthritis. Obesity may contribute, through its metabolic and inflammatory effects, to amplifying symptoms of rheumatic disease and in certain scenarios has been linked with poorer immunotherapy responses (e.g. anti-TNFα in PsA). This should be explained to obese patients and strategies offered on how to lose and maintain an appropriate weight. By contrast, excessive weight loss is also detrimental and low weight (body mass index (BMI) < 20 kg/m²) is associated with an increased risk of fractures. Patients should therefore be advised to maintain BMI within the 20–25 kg/m² range.

**Surgery**

A variety of surgical interventions can relieve pain and conserve or restore function in patients with bone, joint and periarticular disease (Box 26.28).

Soft tissue release and tenosynovectomy can reduce inflammatory symptoms, improve function and prevent or retard tendon damage for variable periods, sometimes indefinitely. Synovectomy does not prevent disease progression, but may be indicated for pain relief when drugs, physical therapy and intra-articular injections have provided insufficient relief. The main approaches for damaged joints are osteotomy (cutting bone to alter joint mechanics and load transmission), excision arthroplasty (removing part or all of the joint), joint replacement (insertion of prosthesis in place of the excised joint) and arthrodesis (joint fusion). Surgical fixation of fractures is frequently required in patients with osteoporosis and other bone diseases.

The main aims of surgery are to provide pain relief and improve function and quality of life. If surgery is to be successful, the aims and consequences of each operation should be considered as part of an integrated programme of management and rehabilitation by multidisciplinary teams of surgeons, allied health professionals and physicians, and carefully explained to the patient. Assessment of motivation, social support and

Paracetamol (1 g up to 4 times daily) is the oral analgesic of first choice for mild to moderate pain. It is thought to work by inhibiting prostaglandins

Non-steroidal anti-inflammatory drugs (NSAIDs)

These are among the most widely prescribed drugs, but their use has declined over recent years because long-term prescription is associated with an increased risk of cardiovascular disease. Oral NSAIDs are useful in the treatment of a range of rheumatic diseases with an inflammatory component. They inhibit the cyclo-oxygenase (COX) and prostaglandin H synthase enzymes, which convert arachidonic acid, derived from membrane phospholipids, to prostaglandins and leukotrienes by the COX and 5-lipoxygenase pathways, respectively (Fig. 26.14). There are two COX isoforms; COX-1 is constitutively expressed in gastric mucosa, platelets and kidneys, and production of prostaglandins at these sites protects against mucosal damage and regulates platelet aggregation and renal blood flow. The COX-2 enzyme is induced at sites of inflammation, producing prostaglandins that cause local pain and swelling. Inflammation also up-regulates COX-2 in the spinal cord, where it modulates pain perception. Ibuprofen, diclofenac and naproxen are non-selective drugs that inhibit both COX enzymes, whereas celecoxib and etoricoxib are

(CNS = central nervous system; COX = cyclo-oxygenase; PPI = proton pump inhibitor)

**Recommendations for the use of NSAIDs**

- Use the lowest dose for the shortest time possible to control symptoms
- Avoid NSAIDs in patients on warfarin
- Allow 2–3 weeks to assess efficacy. If response is inadequate, consider a trial of another NSAID
- Never prescribe more than one NSAID at a time
- Co-prescribe a proton pump inhibitor for patients with risk factors for gastrointestinal adverse effects (see Box 26.30)
- Avoid in patients with cardiovascular disease

**Use of oral NSAIDs in old age**

- **Gastrointestinal complications**: age is a strong risk factor for enteral bleeding and perforation, and for peptic ulceration. Older adults are more likely to die if they suffer NSAID-associated enteral bleeding or perforation.
- **Cardiovascular disease**: use NSAIDs with caution in patients with cardiovascular disease. Therapy with NSAIDs may exacerbate hypertension and heart failure.
- **Renal disease**: use of NSAIDs may cause or worsen renal impairment.

Recommendations for NSAID prescribing are summarised in Box 26.31. Because of the risk of adverse effects, NSAIDs should be used with great care in older patients (Box 26.32).

**Topical agents**

Topical NSAID creams and gels and capsaicin cream can help in the treatment of OA and superficial periarticular lesions affecting hands, elbows and knees. They may be used as monotherapy or as an adjunct to oral analgesics. Topical NSAIDs can penetrate superficial tissues and even reach the joint capsule, though intrasynovial levels mainly reflect blood-borne drug delivery. Capsaicin selectively binds to the protein transient receptor potential vanilloid type 1 (TRPV1), which is a heat-activated calcium channel on the surface of peripheral type C nociceptor fibres. Initial application causes a burning sensation, but continued use depletes presynaptic substance P, with subsequent pain reduction that is optimal after a period of 1–2 weeks. Lidocaine 5% medicated patches are licensed for the treatment of post-herpetic neuropathic pain, but are also used off label for a variety of painful conditions including painful vertebral fractures, sometimes with good effects.

**Disease-modifying anti-rheumatic drugs**

Disease-modifying anti-rheumatic drugs (DMARDs) comprise small-molecule inhibitors of the immune response, glucocorticoids and biologic DMARDs. DMARDs not only improve symptoms but also favourably modify disease progression in a variety of inflammatory rheumatic diseases. Small-molecule inhibitors are either classical DMARDs (cDMARDs), which have relatively non-specific inhibitory effects on the immune response (Box 26.33), or targeted synthetic DMARDs (tsDMARDs), which are designed to inhibit the effects of a specific target molecule (Box 26.34). Biologic DMARDs (‘biologics’) are monoclonal antibodies, fusion proteins or decoy receptors targeted towards specific cytokines, receptors and other cell-surface molecules regulating the immune response (Fig. 26.15). Most cDMARDs have the potential to cause bone marrow suppression or liver dysfunction and require regular blood monitoring, as summarised in Box 26.33. If toxicity occurs, treatment may need to be stopped temporarily and resumed at a lower dose or withdrawn completely if toxicity is severe.

**Classical DMARDs (cDMARDs)**

Methotrexate (MTX) is the core cDMARD in RA, JIA and PsA. It inhibits folic acid reductase, preventing formation of tetrahydrofolate, which is necessary for DNA synthesis in leucocytes and other cells. It is given

selective inhibitors of COX-2. While NSAIDs have anti-inflammatory activity, they are not thought to have a disease-modifying effect in either OA or inflammatory rheumatic diseases.

Non-selective NSAIDs can damage the gastric and duodenal mucosal barrier and are associated with an increased risk of upper gastrointestinal ulceration, bleeding and perforation. The adjusted increased risk (odds ratio) of bleeding or perforation from non-selective NSAIDs is 4–5, though differences exist between NSAIDs (Box 26.29). Dyspepsia is a poor guide to the presence of NSAID-associated ulceration and bleeding, and the principal risk factors are shown in Box 26.30. Co-prescription of a proton pump inhibitor (PPI) or misoprostol (200 µg twice or 3 times daily) reduces the risk of NSAID-induced ulceration and bleeding, but H₂-antagonists in standard doses are ineffective. The COX-2 selective NSAIDs are much less likely to cause gastrointestinal toxicity, but benefit is attenuated in patients on low-dose aspirin. The UK National Institute for Health and Care Excellence (NICE) guidelines advise that a PPI should be co-prescribed with all NSAIDs, including COX-2-selective NSAIDs, even though the risk of gastrointestinal events with these is low. Since chronic PPI therapy is associated with an increased risk of hip fracture, the merits of giving PPI therapy with a COX-2-selective drug need to be carefully considered.

Other side-effects of NSAIDs include fluid retention and renal impairment due to inhibition of renal prostaglandin production, non-ulcer-associated dyspepsia, abdominal pain, altered bowel habit and rashes. Interstitial nephritis, asthma and anaphylaxis can also occur but are rare.
orally or subcutaneously using a variety of dose increment schedules, to a maximum of 25 mg weekly (in adults) and 15 mg/m²/week in JIA, until benefit or toxicity occurs. Folic acid (5 mg/week) should be co-prescribed to be taken the day after MTX since it reduces adverse effects without impairing efficacy. Benefit is usually observed after 4–8 weeks, but treatment should continue for 3 months before reaching the conclusion that MTX has been ineffective. The most common adverse effects are nausea, vomiting and malaise, which usually occur one 1–2 days after the weekly dose. Patients should be warned of drug interaction with sulphonamides and the importance of avoiding excess alcohol, which enhances MTX hepatotoxicity. Acute pulmonary toxicity (pneumonitis) is rare, but can occur at any time during treatment and patients should be warned to stop therapy and seek advice if they develop any respiratory symptoms. If pneumonitis occurs, treatment should be withdrawn and high-dose glucocorticoids given. MTX must be co-prescribed with robust contraception in women of child-bearing potential and treatment must be stopped for 3 months in advance of planning a pregnancy.

Sulfasalazine (SSZ) can be used alone or in combination with other drugs in the treatment of RA and PsA. Its mechanism of action is incompletely understood. Nausea and gastrointestinal intolerance are the main adverse effects but leucopenia, abnormal liver function tests (LFTs) and rashes may occur. The usual starting dose is 500 mg daily, escalating in 500 mg increments every 2 weeks to a maintenance dose of 2–4 g daily until benefit or toxicity occurs. Benefit may be observed after 4–8 weeks, but treatment should be continued for 3 months before concluding that it has been ineffective. Orange staining of urine and contact lenses may occur. SSZ is generally considered to be safe during pregnancy.

Hydroxychloroquine (HCQ) can be used alone or in combination with other drugs in the treatment of RA and SLE in a dose of 200–400 mg daily. It acts by modulating lysosomal activity and autophagy causing inhibition of inflammatory responses. While a wide range of side-effects can theoretically occur, it is generally well tolerated in practice. With long-term use (>5 years) there is a risk of ocular toxicity due to accumulation in the retina, although this is uncommon. It is usual to check visual function before starting treatment and to repeat this periodically while treatment is continued. HCQ is generally considered to be safe during pregnancy.

Leflunomide (LEF) can be used alone or in combination with other drugs for the treatment of RA and PsA in a dose of 10–20 mg/day. It works by inhibiting dihydro-orotate dehydrogenase, an enzyme used by activated lymphocytes to synthesise pyrimidines necessary for DNA synthesis. It has low marrow toxicity, but may cause liver dysfunction, hypertension and hirsutism. It must be co-prescribed with robust contraception in women of child-bearing potential. Treatment must be stopped for a period of 2 years in advance of planning a pregnancy or undergo a washout procedure with cholestyramine to remove the drug from the system.

Azathioprine (AZA) is most commonly used in vasculitis and SLE, often in combination with other drugs. It is metabolised to 6-mercaptopurine (6-MP), which blocks lymphocyte proliferation by inhibiting DNA synthesis. The typical starting dose is 1 mg/kg body weight per day, increasing to 2.5 mg/kg until a response is observed or toxicity occurs. Bone marrow suppression is the most important side-effect, but nausea may also occur. Genetic polymorphisms in the enzyme thiopurine S-methyltransferase (TPMT) influence catabolism of 6-MP and sometimes genetic testing for TPMT variants is done to guide dosages. Allopurinol inhibits catabolism of azathioprine, necessitating a 75% reduction in azathioprine dose.

Cyclophosphamide is a cytotoxic alkylating agent that cross-links DNA and halts cell division, causing immunosuppression. It is mainly used to induce remission in life-threatening systemic vasculitis and SLE. It can be given orally in a dose of 2 mg/kg/day for 3–6 months or intravenously in a dose of 15 mg/kg every 3–4 weeks on 6–8 occasions. Adverse effects include nausea, anorexia, vomiting, bone marrow suppression, cardiac toxicity, alopecia and haemorrhagic cystitis. The risk of cystitis can be mitigated by co-administration of mesna (2-mercaptoethane sulfonate, which binds its urototoxic metabolites) and a high fluid intake.
Mycophenolate mofetil (MMF) works by inhibiting inosine monophosphate dehydrogenase, a rate-limiting enzyme in the synthesis of guanosine nucleotides in lymphocytes. MMF is used in SLE and vasculitis in doses of 2.5–4 mg/kg/day orally. Haematological toxicity is the main adverse effect.

Ciclosporin A is a calcineurin inhibitor that inhibits lymphocyte activation. It is occasionally used in the treatment of RA and PsA at a dose of 2.5–4 mg/kg/day orally.

Glucocorticoids have powerful anti-inflammatory and immunosuppressive effects and have been shown to have disease-modifying effects in various inflammatory rheumatic diseases. They promote apoptosis of many immune cells and activation of a wide range of pro-inflammatory signalling pathways. They are used orally, intravenously, intramuscularly and by intra-articular injection in the treatment of a wide range of inflammatory rheumatic diseases, as well as by local injection in patients with soft tissue rheumatism.

Systemic glucocorticoids are widely used in moderate to high doses to induce remission in early RA, systemic and polyarticular JIA, giant cell arteritis, polymyalgia rheumatica, vasculitis and SLE. Many patients with SLE require low dose maintenance therapy with glucocorticoids and this is sometimes also required in RA when other options are unsatisfactory. They are widely used in the short-term treatment of flares in many inflammatory rheumatic diseases. Glucocorticoids should be used with caution in PsA because of a rebound increase in activity of psoriasis when the effects wear off.

Intra-articular glucocorticoids are employed in the treatment of a wide range of inflammatory arthropathies and are primarily indicated when there are one or two problem joints with persistent synovitis despite good general control of the disease. Methylprednisolone is one of the most widely used, typically in doses of 40–80 mg.

Intramuscular methylprednisolone (80–120 mg) is a useful way of controlling inflammatory arthritis while waiting for the effects of newly introduced drugs to take effect. It can also be helpful in patients with stable disease who have a disease flare where a major change in DMARD strategy is not thought to be necessary.

**Targeted synthetic DMARDs (tsDMARDs)**

These are small molecules targeted at specific intracellular targets involved in regulating the immune response. Treatment costs are high and these drugs are generally used as second-line agents in patients who have responded inadequately to cDMARDs.

Janus-activated kinase (JAK) inhibitors work by inhibiting JAK enzymes, which are a family of intracellular signalling molecules that play a key role in transducing the effects of several pro-inflammatory cytokines. The main adverse effects of JAK inhibitors are an increased risk of infections, and because of this, it is customary to screen patients for evidence of occult infection with HIV, hepatitis C, hepatitis B and previous TB before commencing therapy. Currently there are four drugs in this class. Tofacitinib (5 mg twice daily or 10 mg daily) is indicated for adults with RA and PsA. It is usually prescribed in combination with MTX, but can be used as monotherapy in patients where MTX is poorly tolerated or contraindicated. Baricitinib (2–4 mg once daily) and filgotinib (200 mg daily) are both indicated for RA. Upadacitinib (15 mg daily) is also indicated as monotherapy or in combination with MTX, for RA, PsA and AxSpA. Tofacitinib requires long-term blood monitoring for marrow and liver toxicity, but this is not required with the other JAK inhibitors once the first 3 months of therapy have been completed.

Apremilast is used in the treatment of PsA. It is a small molecule inhibitor of phosphodiesterase 4, an enzyme that breaks down cyclic adenosine monophosphate (cAMP). This suppresses production of pro-inflammatory cytokines, thereby reducing inflammation. Apremilast is given orally in a dose of 30 mg twice daily. The main adverse effects are gastrointestinal upset, weight loss and an increased risk of depression.
Biologic DMARDs

‘Biologics’ (monoclonal antibodies, fusion proteins or decoy receptors) are given either as self-administered subcutaneous injections every 1–4 weeks or as infusions every few weeks. The main adverse effect of biologics as a class is an increased risk of infections, and screening for occult infections is generally performed before commencing therapy as described for JAK inhibitors. Biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. Treatment costs are higher than with cDMARDs and tsDMARDs and many countries have set guidelines and funding restrictions that limit their use. Their mechanisms of action, dosages and indications are summarised in Box 26.35.

TNF-α inhibitors. Most drugs in this class are monoclonal antibodies that bind to and neutralise TNF-α, but etanercept is a decoy receptor that prevents TNF-α binding to its receptor. Anti-TNF-α therapy is frequently used as the first-line biologic in RA, JIA and PsA when cDMARD therapy has been incompletely effective and as first line biologic in axSpA/AS in patients who have failed to respond adequately to NSAID therapy. Anti-TNF-α is contraindicated in patients with active infections and those with indwelling catheters, due to the high risk of infection. Other contraindications are heart failure (New York Heart Association grade 3 or 4) and multiple sclerosis, both of which may be worsened by treatment. Anti-TNF-α therapies can be used during pregnancy, but should be stopped in the third trimester since most cross the placenta and can cause immunosuppression in the neonate. An exception is certolizumab, which does not cross the placenta and can be used safely throughout pregnancy.

Rituximab is an antibody directed against the CD20 receptor, which is expressed on B lymphocytes and immature plasma cells. Rituximab causes profound B cell lymphopenia and immature plasma cell death. Rituximab is indicated in RA patients where response to cDMARDs has been inadequate and in children with ANCA-associated vasculitis. In RA, treatment can be repeated when signs of improvement are wearing off (6 months to 1 year or longer). In ANCA-positive vasculitis, a single cycle of treatment may last for up to 18 months. Adverse effects include hypogammaglobulinaemia, infusion reactions, an increased risk of infections and, rarely, progressive multifocal leucoencephalopathy (PML), a serious and potentially fatal infection of the central nervous system caused by reactivation of JC virus.

Belimumab is a monoclonal antibody that blocks the effects of the cytokine B cell-activating factor of the TNF family (BAFF), which is required for B cell survival and function. It is indicated in juvenile and adult patients with SLE who have had an inadequate response to cDMARDs. The main adverse effects are an increased risk of infection, leucopenia and hypersensitivity reactions following infusion.

Abatacept is a fusion protein in which the Fc domain of IgG has been combined with the extracellular domain of CTLA4, which blocks T-cell activation by acting as a decoy for CD28, a co-stimulatory molecule necessary for T-cell activation. It is indicated for RA and PsA and polyclonal onset JIA where the response to cDMARDs is inadequate. The main adverse effect is an increased risk of infections.

IL-6 inhibitors. There are two drugs in this class, Tocilizumab is a monoclonal antibody that competes with IL-6 for binding to the IL-6 receptor, thereby inhibiting IL-6 signalling. It is indicated in RA with or without MTX after inadequate response to cDMARDs and in patients 12 years of age and older with systemic JIA, who have responded inadequately to therapy with NSAIDs and systemic glucocorticoids. It is also indicated as a steroid-sparing agent in GCA. Sarilumab is a monoclonal antibody (lgG1) that works in a similar way to tocilizumab, which is licensed for treating adult RA (with concomitant MTX), where there has been an inadequate response to cDMARDs. Adverse effects of both agents include leucopenia, abnormal LFTs, hypercholesterolaemia and hypersensitivity reactions. Both drugs should be avoided during pregnancy if possible.

Ustekinumab is an antibody to p40, which is a subunit shared by the cytokines IL-23 and IL-12. It acts as an inhibitor of both IL-12 and IL-23 signalling and is indicated in adults with PsA who have not responded adequately to cDMARDs. It can be used as monotherapy or in combination with MTX. Adverse effects include an increased risk of infections, hypersensitivity reactions and an exfoliative dermatitis. Guselkumab is an antibody directed against the p19 protein of IL-23, which acts as a specific inhibitor of IL-23 signalling. It is effective in the treatment of PsA and can be used alone or in combination with MTX.

IL-17 inhibitors. There are two drugs in this class; secukinumab is a monoclonal antibody to IL-17A and ixekizumab, which binds both
IL-17A and IL-17A/F. These drugs are indicated in adults with PsA and axSpA who have not responded adequately to cDMARDs and/or anti-TNF-α. Adverse effects include an increased risk of triggering bouts of IBD, infections, nasopharyngitis and headache. Adverse effects include infections and exacerbation of IBD. Clinical experience indicates that these drugs are probably safe during pregnancy, but information is limited.

**Interleukin-1 inhibitors.** There are two drugs in this class. Anakinra is a human IL-1 receptor antagonist, which neutralises the effects of interleukin-1α (IL-1α) and interleukin-1β (IL-1β) by inhibiting binding to interleukin-1 type I receptor (IL-1RI). Its most frequent use is for the treatment of adult-onset Still’s disease and for periodic fever syndromes (p. 76). It has some efficacy in RA, but is seldom used since other drugs are more effective. Other indications include acute gout, although it is not licensed for this condition, and chronic non-infectious osteomyelitis (see p. 1062). Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia. Canakinumab is a monoclonal antibody directed against IL-1β, which is indicated for the treatment of systemic JIA (Still’s disease), adult-onset Still’s disease and acute flares of gout resistant to other treatments. The usual maintenance dose in adults is 150–300 mg every 8 weeks. Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia.

### Osteoarthritis

Osteoarthritis (OA) is by far the most common form of arthritis and is a major cause of pain and disability in older people. It is characterised by focal loss of articular cartilage, subchondral osteosclerosis, osteophyte formation at the joint margin and remodelling of joint contour with enlargement of affected joints.

**Epidemiology**

The prevalence rises progressively with age and it has been estimated that 45% of all people develop knee OA and 25% hip OA at some point during life. Although some are asymptomatic, the lifetime risk of having a total hip or knee replacement for OA in someone aged 50 is about 11% for women and 8% for men in the UK. There are major ethnic differences in susceptibility: the prevalence of hip OA is lower in Africa, China, Japan and South Asia than in European countries, while that of knee OA is higher.

**Pathophysiology**

OA is a complex disorder, with both genetic and environmental components (Box 26.36). Family-based studies have estimated that the heritability of OA ranges from about 43% at the knee to between 60% and 65% at the hip and hand, respectively. In most cases, the inheritance is polygenic and mediated by several genetic variants of small effect. OA can be a component of multiple epiphyseal dysplasias, which are caused by single gene mutations affecting components of cartilage matrix. Structural abnormalities, such as slipped femoral epiphysis and developmental dysplasia of the hip, are also associated with a high risk of OA, presumably due to abnormal load distribution across the joint. Similar mechanisms probably explain the increased risk of OA in patients with limb deformity secondary to Paget’s disease of bone. Biomechanical factors play an important role in OA related to certain occupations, such as farmers (hip OA), miners (knee OA) and elite or professional athletes (knee and ankle OA). It has been speculated that the higher prevalence of knee OA in South and East Asia might be accounted for by squatting. There is also a high risk of knee OA in people who have had destabilising injuries, such as cruciate ligament rupture, and those who have had meniscectomy. For most individuals, however, participation in recreational sport does not appear to increase the risk significantly. There is a strong association between obesity and OA, particularly of the hip. This is thought to be due partly to biomechanical factors, but it has also been speculated that cytokines released from adipose tissue may play a role. Oestrogen appears important; lower rates of OA have been observed in women who use hormone replacement therapy (HRT), while women who receive aromatase inhibitor therapy for breast cancer often experience a flare in symptoms of OA.

Degeneration of articular cartilage is the defining feature of OA. Under normal circumstances, chondrocytes are terminally differentiated cells, but in OA they start dividing to produce nests of metabolically active cells (Fig. 26.16A). Initially, matrix components are produced by these cells at an increased rate, but at the same time there is accelerated degradation of the major structural components of cartilage matrix, including aggrecan and type II collagen (see Fig. 26.5). Eventually, the concentration of aggrecan in cartilage matrix falls and makes the cartilage vulnerable to load-bearing injury. Fissuring of the cartilage surface (“fibrillation”) then occurs, leading to the development of deep vertical clefts (Fig. 26.16B), localised chondrocyte death and decreased cartilage thickness. This is initially focal, mainly targeting the maximum load-bearing part of the joint, but eventually large parts of the cartilage surface are damaged. CPP and basic calcium phosphate crystals often become deposited in the abnormal cartilage.

OA is also accompanied by abnormalities in subchondral bone, which becomes sclerotic and the site of subchondral cysts (Fig. 26.16C). Bioresorption is produced at the joint margin, which undermines endochondral ossification to form osteophytes. Bone remodelling and cartilage thinning slowly alter the shape of the OA joint, increasing its surface area. It is almost as though there is a homeostatic mechanism operative in

---

**Fig. 26.16 Pathological changes in osteoarthritis.** A Abnormal nests of proliferating chondrocytes (arrows) interspersed with matrix devoid of normal chondrocytes. B Fibrillation of cartilage in osteoarthritis (OA). C X-ray of knee joint affected by OA, showing osteophytes at joint margin (white arrows), subchondral sclerosis (black arrows) and a subchondral cyst (open arrow).
OA that causes enlargement of the failing joint to spread the mechanical load over a greater surface area. Patients with OA also have higher BMD values at sites distant from the joint and this is particularly associated with osteophyte formation. This is in keeping with observations made in epidemiological studies that show that patients with OA are partially protected from developing osteoporosis and vice versa. This is likely to be due to the fact that the genetic factors that predispose to osteoporosis might be protective for OA.

The synovium in OA is often hyperplastic and may be the site of inflammatory change, but to a much lesser extent than in RA and other inflammatory arthropathies. Osteochondral bodies commonly occur within the synovium, reflecting chondroid metaplasia or secondary uptake and growth of damaged cartilage fragments. The outer capsule also thickens and contracts, usually retarding the stability of the remodeling joint. The muscles surrounding affected joints commonly show evidence of wasting and non-specific type II fibre atrophy.

**Clinical features**

Osteoarthritis has a characteristic distribution, mainly targeting the hips, knees, PIP and DIP joints of the hands, neck and lumbar spine (see Fig. 26.10). The main presenting symptoms are pain and functional restriction. The causes of pain in OA are not completely understood, but may relate to increased pressure in subchondral bone (mainly causing night pain), trabecular microfractures, capsular distension and low-grade synovitis. Pain may also result from bursitis and enthesopathy secondary to altered joint mechanics. Typical OA pain has the characteristics listed in Box 26.37. For many people, functional restriction of the hands, knees or hips is an equal, if not greater, problem than pain. The clinical findings vary according to severity, but are principally those of joint damage.

The correlation between the presence of structural change, as assessed by imaging, and symptoms such as pain and disability varies markedly according to site. It is stronger at the hip than at the knee and weak at most small joints. This suggests that the risk factors for pain and disability may differ from those for structural change. At the knee, for example, reduced quadriceps muscle strength and adverse psychosocial factors (anxiety, depression) correlate more strongly with pain and disability than the degree of radiographic change.

Radiological evidence of OA is very common in middle-aged and older people, and the disease may coexist with other conditions, so it is important to remember that pain in a patient with OA may be due to another cause.

**Generalised nodal OA**

Characteristics of this common form of OA are shown in Box 26.38. Some patients are asymptomatic whereas others develop pain, stiffness and swelling of one or more PIP and DIP joints of the hands from the age of about 40 years onwards. Gradually, these develop posterolateral swellings on each side of the extensor tendon, which slowly enlarge and harden to become Heberden’s (DIP) and Bouchard’s (PIP) nodes (Fig. 26.17). Typically, each joint goes through a phase of episodic symptoms (1–5 years) while the node evolves and OA develops. Once OA is fully established, symptoms may subside and hand function often remains good. Affected joints are enlarged as a result of osteophyte formation and often show characteristic lateral deviation, reflecting the asymmetric focal cartilage loss of OA (Fig. 26.18). Involvement of the first carpometacarpal (CMC) joint is also common, leading to pain on trying to open bottles and jars, and functional impairment. Clinically, it may be detected by the presence of crepitus on joint movement and squaring of the thumb base.

Generalised nodal OA has a very strong genetic component: the daughter of an affected mother has a 1 in 3 chance of developing nodal OA herself. People with nodal OA are also at increased risk of OA at other sites, especially the knee.

**Knee OA**

At the knee, OA principally targets the patello-femoral and medial tibio-femoral compartments, but eventually spreads to affect the whole of the joint. (Fig. 26.19). It may be isolated or occur as part of generalised nodal OA. Most patients have bilateral and symmetrical involvement. In men, trauma is often a more important risk factor and may result in unilateral OA.

The pain is usually localised to the anterior or medial aspect of the knee and upper tibia. Patello-femoral pain is usually worse going up and down stairs or inclines. Posterior knee pain suggests the presence of a complicating popliteal cyst (Baker’s cyst). Prolonged walking, rising from a chair, getting in or out of a car, or bending to put on shoes and socks may be difficult. Local examination findings may include:

- a jerky, asymmetric (antalgic) gait with less time weight-bearing on the painful side
- a varus (Fig. 26.20) or, less commonly, valgus and/or a fixed flexion deformity
- joint-line and/or periarticular tenderness (secondary anserine bursitis and medial ligament enthesopathy (see Box 26.25), causing tenderness of the upper medial tibia)
Fig. 26.18 X-ray appearances in hand osteoarthritis. There is joint space narrowing affecting the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints in both hands. There are typical articular subchondral and ‘gull wing’ appearances to some osteoarthritis-affected joints, as well as osteophyte formation that is most marked at the second DIP joints bilaterally and the first PIP joint on the right hand (arrows).

Fig. 26.19 X-ray appearances in knee osteoarthritis. A Advanced osteoarthritis showing almost complete loss of joint space affecting both compartments and sclerosis of subchondral bone. B Skyline view of the patella femoral joint in a patient with severe patello-femoral osteoarthritis. There is almost complete loss of joint space and lateral displacement of the patella.

- weakness and wasting of the quadriceps muscle
- restricted flexion and extension with crepitus
- bony swelling around the joint line.

CPP crystal deposition in association with OA is common at the knee. This may result in a more overt inflammatory component (stiffness, effusions) and super-added acute attacks of synovitis (acute CPP crystal arthritis), which may be associated with more rapid radiographic and clinical progression.

Fig. 26.20 Typical varus knee deformity resulting from marked medial tibio-femoral osteoarthritis.

Fig. 26.21 X-ray of hip showing changes of osteoarthritis. Note the superior joint space narrowing (N), subchondral sclerosis (S), marginal osteophytes (O) and cysts (C).

Hip OA

Hip OA most commonly targets the superior aspect of the joint (Fig. 26.21). It is often unilateral at presentation, frequently progresses with superolateral migration of the femoral head and has a poor prognosis. The less common central (medial) OA shows more central cartilage loss and is largely confined to women. It is often bilateral at presentation and can be associated with generalised nodal OA. It has a better prognosis than superior hip OA and progression to axial migration of the femoral head is uncommon.

The hip shows the best correlation between symptoms and radiographic change. Hip pain is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin. Lateral hip pain, worse on lying on that side with tenderness over the greater trochanter, suggests secondary trochanteric bursitis. Common functional difficulties are the same as for knee OA; in addition, restricted hip abduction in women may cause pain during sexual intercourse. Examination may reveal:

- an antalgic gait
- weakness and wasting of quadriceps and gluteal muscles
Fig. 26.22 X-ray of spine showing typical changes of osteoarthritis. Cervical spondylosis showing disc space narrowing between C6 and C7, osteophytes at the anterior vertebral body margins (thin arrows) and osteosclerosis at the apophyseal joints (thick arrow).

### 26.39 Causes of early-onset osteoarthritis

**Monoarticular**
- Previous trauma, localised instability

**Pauciarticular or polyarticular**
- Juvenile idiopathic arthritis
- Metabolic or endocrine disease:
  - Haemochromatosis
  - Ochronosis
  - Acromegaly
  - Alkaptonuria
- Spondylo-epiphysial dysplasia
- Late osteonecrosis
- Neuropathic joint
- Kashin-Beck disease

- pain and restriction of internal rotation with the hip flexed – the earliest and most sensitive sign of hip OA; other movements may subsequently be restricted and painful
- anterior groin tenderness just lateral to the femoral pulse
- fixed flexion, external rotation deformity of the hip
- ipsilateral leg shortening with severe joint attrition and superior femoral migration.

Obesity is associated with more rapid progression of hip OA.

### Spine OA

The cervical and lumbar spine are the sites most often targeted by OA, where it is referred to as cervical spondylosis and lumbar spondylosis, respectively (Fig. 26.22). Spine OA may occur in isolation or as part of generalised OA. The typical presentation is with pain localised to the low back region or the neck, although radiation of pain to the arms, buttocks and legs may also occur due to nerve root compression. The pain is typically relieved by rest and worse on movement. On physical examination, the range of movement may be limited and loss of lumbar lordosis is typical. The straight leg-raising test or femoral stretch test may be positive and neurological signs may be seen in the legs where there is complicating spinal stenosis or nerve root compression.

### Early-onset OA

Rarely, OA may present before the age of 45. In most cases, a single joint is affected and there is a clear history of previous trauma. However, specific causes of OA need to be considered in people with early-onset disease affecting several joints, especially those not normally targeted by OA, in which case rare causes need to be considered (Box 26.39).

Kashin-Beck disease is a rare form of OA that occurs in children, typically between the ages of 7 and 13, in some regions of China. The cause is unknown, but suggested predisposing factors are selenium deficiency and contamination of cereals with mycotoxin-producing fungi.

### Erosive OA

This term is used to describe an unusual group of patients with hand OA who have a more prolonged symptom phase, more overt inflammation, more disability and worse outcome than those with nodal OA. Distinguishing features include preferential targeting of PIP joints, subchondral erosions on X-rays, occasional ankylosis of affected joints and lack of association with OA elsewhere. It is unclear whether erosive OA is part of the spectrum of hand OA or a discrete subset.

### Investigations

A plain X-ray of the affected joints should be performed and often will show one or more of the typical features of OA (see Fig. 26.16 and Figs. 26.18-26.22). In addition to providing diagnostic information, X-rays are of value in assessing the severity of structural change, which is helpful if joint replacement surgery is being considered. Non-weight-bearing postero-anterior views of the pelvis are adequate for assessing hip OA. Patients with suspected knee OA should have standing anteroposterior X-rays taken to assess tibio-femoral cartilage loss and a flexed skyline view to assess patello-femoral involvement. Spine OA can often be diagnosed on a plain X-ray, which typically shows evidence of disc space narrowing and osteophytes. If nerve root compression or spinal stenosis is suspected, MRI should be performed.

Routine biochemistry, haematology and autoantibody tests are usually normal, though inflammatory OA can be associated with a mild acute phase response. Synovial fluid aspirated from an affected joint is viscous, with a low cell count.

Unexplained early-onset OA requires additional investigation, guided by the suspected underlying condition. X-rays may show typical features of dysplasia or osteonecrosis, widening of joint spaces in acromegaly, multiple cysts, chondrocalcinosis and MCP joint involvement in haemochromatosis or disorganised architecture in neuropathic joints.

### Management

Treatment follows the general principles outlined earlier this chapter. Measures that are pertinent in older people are summarised in Box 26.40.

### Education

It is important to explain the nature of the condition fully, outlining the role of relevant risk factors such as obesity, heredity and trauma. The patient should be informed that established structural changes are permanent and that, although a cure is not possible, pain and function can often be improved. The prognosis should also be discussed, mentioning that it is generally good for nodal hand OA and better for knee than hip OA.
Lifestyle advice
Weight loss has a substantial beneficial effect on symptoms if the patient is obese and is probably one of the most effective treatments available for OA of the lower limbs. Strengthening and aerobic exercises also have beneficial effects in OA and should be advised, preferably with reinforcement by a physiotherapist. Quadriceps strengthening exercises are particularly beneficial in knee OA. Shock-absorbing footwear, pacing of activities, use of a walking stick for painful knee or hip OA, and provision of built-up shoes to equalise leg lengths can all improve symptoms.

Non-pharmacological therapy
Acupuncture and transcutaneous electrical nerve stimulation (TENS) can be effective in knee OA. Local physical therapies, such as heat or cold, can sometimes give temporary relief.

Pharmacological therapy
If symptoms do not respond to non-pharmacological measures, paracetamol should be tried. Addition of a topical NSAID and then capsaicin for knee and hand OA can also be helpful. Oral NSAIDs should be considered in patients who remain symptomatic. These drugs are significantly more effective than paracetamol and can be successfully combined with paracetamol or compound analgesics if the pain is severe. Strong opiates may occasionally be required. Antineuropathic drugs, such as amitriptyline, gabapentin and pregabalin, are sometimes used in patients with symptoms that are difficult to control, but the evidence base for their use is poor. Neutralising antibodies to nerve growth factor have been developed and are an effective treatment for pain in OA, but they are not yet licensed for routine clinical use.

Intra-articular injections
Intra-articular glucocorticoid injections are effective in the treatment of knee OA and are also used for symptomatic relief in the treatment of OA at the first CMC joint. The duration of effect is usually short, but trials of serial glucocorticoid injections every 3 months in knee OA have shown efficacy for up to 1 year. Intra-articular injections of hyaluronic acid can help to an extent in knee OA, but the treatment is expensive and the effect short-lived. In the UK they have not been considered to be cost-effective by NICE.

Neutraceuticals
Chondroitin sulphate and glucosamine sulphate have been used alone and in combination for the treatment of knee OA. There is evidence from randomised controlled trials that these agents can improve knee pain to a small extent (3%–5%) compared with placebo.

Surgery
Surgery should be considered for patients with OA whose symptoms and functional impairment impact significantly on their quality of life despite optimal medical therapy and lifestyle advice. Total joint replacement surgery is by far the most common surgical procedure for patients with OA. It can transform the quality of life for people with severe knee or hip OA and is indicated when there is significant structural damage on X-ray. Although surgery should not be undertaken at an early stage during the development of OA, it is important to consider it before functional limitation has become advanced since this may compromise outcome. Patient-specific factors, such as age, gender, smoking and presence of obesity, should not be barriers to referral for joint replacement.

Only a small proportion of patients with OA progress to the extent that total joint replacement is required, but OA is by far the most frequent indication for this. Over 96% of joint replacements continue to function well into the second decade after surgery and most provide life-long, pain-free function. Up to 20% of patients are not satisfied with the outcome, however, and a few experience little or no improvement in pain. Other surgical procedures are performed much less frequently. Resurfacing of the femoral head can be considered for younger patients with hip OA (age <60) as an alternative to total joint replacement. Tibial osteotomy represents an alternative to total joint replacement in younger patients with knee OA and can be effective at improving pain by altering alignment of the lower leg. Cartilage repair is sometimes performed to treat focal cartilage defects resulting from joint injury.

Crystal-induced arthritis
A variety of crystals can deposit in and around joints and structures in the spine and cause an acute inflammatory or even chronic inflammatory arthritis or disease (Box 26.41). Several factors influence crystal formation (Fig. 26.23). There must be sufficient concentration of the chemical components (ionic product), but whether a crystal then forms depends on the balance of tissue factors that promote and inhibit crystal nucleation and growth. The inflammatory potential of crystals resides in their physical irregularity and high negative surface charge, which can induce inflammation and damage cell membranes. Crystals may also cause mechanical damage to tissues and act as wear particles at the joint surface. They can reside in cartilage or tendon for years without causing inflammation or symptoms and it is only when they are released that they trigger inflammation. This may occur spontaneously but can also result from local trauma, rapid changes in the concentration of the components that form crystals, or in association with an acute phase response triggered by intercurrent illness or surgery. In the longer term, a reduction in concentrations of the solutes that form crystals causes dissolution of crystals and remission of the arthritis.

Gout
Gout is the most common inflammatory arthritis in men and in older women though robust epidemiological data on the prevalence of CPPD are lacking. Gout is caused by deposition of monosodium urate monohydrate crystals in and around synovial joints.

Epidemiology
The prevalence of gout is approximately 1%–2%, with a greater than 5:1 male preponderance. Gout has become progressively more common over recent years in affluent societies due to the increased prevalence of obesity and metabolic syndrome, of which hyperuricaemia is
an integral component. The risk of developing gout increases with age and with serum uric acid (SUA) levels. These are normally distributed in the general population and hyperuricaemia is defined as an SUA of more than 2 standard deviations above the mean for the population. SUA levels are higher in men, increase with age and are positively associated with body weight. Levels are higher in some ethnic groups (such as Maoris and Pacific islanders). Although hyperuricaemia is a strong risk factor for gout, only a minority of hyperuricaemic individuals actually develop gout.

**Pathophysiology**

About one-third of the body uric acid pool is derived from dietary sources and two-thirds from endogenous purine metabolism (Fig. 26.24). The concentration of uric acid in body fluids depends on the balance between endogenous synthesis and elimination by the kidneys (two-thirds) and gut (one-third). Purine nucleotide synthesis and degradation are regulated by a network of enzyme pathways, but xanthine oxidase plays a pivotal role in catalysing the conversion of hypoxanthine to xanthine and xanthine to uric acid.

The causes of hyperuricaemia are shown in Box 26.42. In over 90% of patients, the main abnormality is reduced uric acid excretion by the kidney, which is genetically determined. Impaired renal excretion of urate also accounts for the occurrence of hyperuricaemia in chronic renal failure and for hyperuricaemia associated with thiazide diuretic therapy.

Other risk factors for gout include metabolic syndrome, high alcohol intake (predominantly beer, which contains guanosine), generalised OA and a diet relatively high in game, offal, seafood, red meat and fructose, or low in vitamin C. Lead poisoning may cause gout (saturnine gout). The association between OA and gout is thought to be due to a reduction in levels of proteoglycan and other inhibitors of crystal formation in osteoarthritic cartilage, predisposing to crystal formation.

Some patients develop gout because they over-produce uric acid. The mechanisms are poorly understood, except in the case of a few single gene disorders where there are mutations in genes that regulate purine metabolism (see Box 26.42). Lesch–Nyhan syndrome is an X-linked recessive form of gout that is also associated with mental retardation, self-mutilation and choreoathetosis. An inherited cause should be suspected if other clinical features are present or there is an early age at onset with a positive family history. Severe hyperuricaemia can also occur in patients with haematological and other cancers who are undergoing chemotherapy due to increased purine turnover (tumour lysis

---

**Fig. 26.23** Mechanisms of crystal formation.

**Fig. 26.24** Uric acid metabolism. The main pathways for uric acid production and elimination are shown, along with the site of action for urate-lowering therapies.

### 26.42 The main causes of hyperuricaemia and gout

#### Diminished renal excretion
- Increased renal tubular reabsorption*
- Renal failure
- Lead toxicity
- Lactic acidosis
- Alcohol

#### Increased intake
- Game
- Shellfish
- Offal
- Red meat

#### Increased production
- Myeloproliferative and lymphoproliferative disease
- Psoriasis
- High fructose intake
- Glycogen storage disease

#### Drugs:
- Thiazide and loop diuretics
- Low-dose aspirin
- Ciclosporin
- Pyrazinamide
- Cancer chemotherapy
- ACE inhibitors

#### Inherited disorders:
- Lesch–Nyhan syndrome (HPRT mutations)
- Phosphoribosyl pyrophosphate synthetase 1 mutations

*Usually genetically determined (see text).

(ACE = angiotensin-converting enzyme; HPRT = hypoxanthine guanine phosphoribosyl transferase)
syndrome). This acute rise in urate seldom, if ever, causes gout but can cause acute kidney injury.

**Clinical features**

The classical presentation is with an acute monoarthritis, which affects the first MTP joint in over 50% of cases (Fig. 26.25). Other common sites are the ankle, midfoot, knee, small joints of hands, wrist and elbow. The axial skeleton and large proximal joints are rarely involved. Typical features include:

- rapid onset, reaching maximum severity in 2–6 hours, worse in the early morning
- severe pain, often described as the ‘worst pain ever’
- extreme tenderness, so the patient is unable to wear a sock or to let bedding rest on the joint
- marked swelling with overlying red, shiny skin
- self-limiting over 5–14 days, with complete resolution.

During the attack, the joint shows signs of marked synovitis, swelling and erythema. There may be accompanying fever, malaise and even delirium, especially if a large joint such as the knee is involved. As the attack subsides, pruritus and desquamation of overlying skin are common. The main differential diagnosis is septic arthritis, cellulitis and reactive arthritis. Acute attacks may also manifest as bursitis, or tenosynovitis. Sometimes an acute attack will be followed by further attacks in other joints a few days later (cluster attacks), the first possibly acting as a trigger. Simultaneous polyarticular attacks are unusual.

Some people never have a second episode and in others several years may elapse before a second attack occurs. Patients with repeated attacks may progress to chronic gout, with chronic pain, joint damage, deformity and functional impairment. Patients with uncontrolled hyperuricaemia who suffer multiple attacks of acute gout may also progress to chronic gout.

The presentation of gout in old age may be atypical, with chronic symptoms rather than acute attacks (Box 26.43).

Crystals may be deposited in the joints and soft tissues to produce irregular firm nodules called tophi. These have a predilection for the extensor surfaces of fingers, hands, forearm, elbows, Achilles tendons and sometimes the helix of the ear. Tophi have a white colour (Fig. 26.26), differentiating them from rheumatoid nodules. Tophi can ulcerate, discharging white gritty material, become infected or induce a local inflammatory response, with erythema and pus in the absence of secondary infection. They are usually a feature of long-standing gout, but can sometimes develop within 12 months in patients with chronic renal failure. Occasionally, tophi may develop in the absence of previous acute attacks, especially in patients on thiazide therapy who have coexisting OA.

In addition to causing musculoskeletal disease, chronic hyperuricaemia may be complicated by renal stone formation and, if severe, renal impairment due to the development of interstitial nephritis as a result of urate deposition in the kidney. This is particularly common in patients with chronic tophaceous gout who are on diuretic therapy.

**Investigations**

The diagnosis of gout can be confirmed by the identification of urate crystals in the aspirate from a joint, bursa or tophus (see Fig. 26.6A). In acute gout, the synovial fluid may be turbid due to an elevated neutrophil count. In chronic gout, the appearance is more variable, but occasionally the fluid appears white due to the presence of urate crystals. Between attacks, aspiration of an asymptomatic first MTP joint or knee may still reveal crystals.

A biochemical screen, including renal function, uric acid, glucose and lipid profile, should be performed because of the association with metabolic syndrome. Hyperuricaemia is usually present in gout, but levels may be normal during an attack because serum urate falls during inflammation. Acute gout is characterised by an elevated ESR and CRP and with a neutrophilia, all of which return to normal as the attack subsides. Tophaceous gout may be accompanied by a modest but chronic elevation in ESR and CRP.

X-rays are usually normal in acute gout, but well-demarcated erosions may be seen in patients with chronic or tophaceous gout (Fig. 26.27). Tophi may also be visible on X-rays as soft tissue swellings. In late disease, destructive changes may occur that are similar to those in other forms of advanced inflammatory arthritis.

**Management**

Management should focus on first dealing with the acute attack and then giving prophylaxis to lower SUA and prevent further attacks.
Acute gout

Oral colchicine given in doses of 0.5 mg 2–4 times daily is the treatment of first choice in acute gout. It works by inhibiting the inflamma-
some (see Fig. 4.2), which reduces IL-1β production by macrophages. The most common adverse effects are nausea, vomiting and diarrhoea. Oral NSAIDs are also effective, but are used less commonly since many patients affected by acute gout have coexisting cardiovascular, cerebrovascular or chronic kidney disease. Oral prednisolone (15–20 mg daily for 2–3 days) or intramuscular methyldprednisolone (80–120 mg daily) are highly effective and are a good choice in older patients where there is an increased risk of toxicity with colchicine and NSAID (see Box 26.43). IL-1 inhibition with anakinra or canakinumab (see Box 26.35) is effective but both treatments are expensive and so are seldom given. Local ice packs can also be used for symptomatic relief. Patients with recurrent episodes can keep a supply of an NSAID, colchicine or prednisolone and take it as soon as the first symptoms occur, continuing until the attack resolves. Joint aspiration can give pain relief, particularly if a large joint is affected, and may be combined with an intra-articular glucocorticoid injection if the diagnosis is clear and infection can be excluded.

Prophylaxis

Patients who have had a single attack of gout do not necessarily need to be given urate-lowering therapy, but it should be offered to individu-
als who have more than one acute attack within 12 months and those with complications such as tophi or erosions (Box 26.44). The long-term therapeutic aim is to prevent attacks occurring by bringing SUA below the level at which monosodium urate monohydrate crystals form. A ther-
aputic target of <300 μmol/L (5 mg/dL) is recommended in the British Society of Rheumatology guidelines, whereas the European League Against Rheumatism guidelines recommend a threshold of <360 μmol/L (6 mg/dL) or <300 μmol/L (5 mg/dL) in those with severe gout.

Allopurinol is the drug of first choice. It inhibits xanthine oxidase, which reduces the conversion of hypoxanthine and xanthine to uric acid. The recommended starting dose is 100 mg daily, or 50 mg in older patients and in renal impairment. The dose of allopurinol should be increased by 100 mg every 4 weeks (50 mg in older patients and those with renal impairment) until the target uric acid level is achieved, side-effects occur or the maximum recommended dose is reached (900 mg/day). Acute flares of gout often follow initiation of urate-lowering therapy. The patient should be warned about this and told to continue therapy, even if an attack occurs. The risk of flares can be reduced by prophylaxis with oral colchicine (0.5–1 mg daily) or an NSAID for the first few months. Alternatively, patients can be given a supply of colchicine, an NSAID or prednisolone to be taken at the first sign of an acute attack. In the longer term, annual monitoring of uric acid levels is recommended. In most patients, urate-lowering therapy needs to be continued indefinitely.

Febuxostat also inhibits xanthine oxidase. It is typically used in patients with an inadequate response to allopurinol and when allopurinol is con-
traindicated or causes adverse effects. Febuxostat undergoes hepatic metabolism and no dose adjustment is required for renal impairment. It is more effective than allopurinol, but commonly provokes acute attacks when therapy is initiated. The usual starting dose is 40–80 mg daily, increasing to 120 mg daily in patients with an inadequate response. Prophylaxis against acute attacks should be given on initiating therapy, as described for allopurinol.

Uricosuric drugs, such as probenecid, sulfipyrazone and benzbro-
marone, lower urate levels but are seldom used in routine clinical prac-
tice. They are contraindicated in urate over-producers and those with renal impairment or urithiasis and require patients to maintain a high fluid intake to avoid uric acid crystallisation in the renal tubules.

Pegloticase is a biologic treatment comprised of the enzyme uricase conjugated to monomethoxypolyethylene glycol. It breaks down uric acid and is indicated for the treatment of tophaceous gout resistant to stand-
ard therapy and is administered as an intravenous infusion every 2 weeks for up to 6 months. It is highly effective at controlling hyperuricaemia and can cause regression of tophi. The main adverse effects are infusion reactions (which can be treated with antihistamines or glucocorticoids) and flares of gout during the first 3 months of therapy. A limiting factor for longer-term treatment is the development of antibodies to pegloticase, which occur in a high proportion of cases and are associated with an impaired therapeutic response.

Lifestyle measures are as important as drug therapy in treatment of gout. Patients should be advised to lose weight if appropriate and reduce excessive alcohol intake, especially beer. Several antihypertensive drugs, including thiazides, β-adrenoceptor antagonists (β-blockers) and angioten-
sin converting enzyme (ACE) inhibitors, increase uric acid levels, whereas losartan has a uricosuric effect and should be substituted for other drugs if possible. Patients should avoid large amounts of seafood and offal, which have a high purine content, but a highly restrictive diet is not necessary.

Calcium pyrophosphate deposition (CPPD) disease

Calcium pyrophosphate deposition (CPPD) disease encompasses a range of clinical presentations. Crystals can deposit in articular cartil-
lage, synovium, entheses, tendons and ligaments – both axial and peri-
pheral skeletal sites. The acute form of CPPD disease is acute calcium pyrophosphate deposition (CPP) crystal arthritis ("pseudogout"). Acute CPP crystal arthritis is rare under the age of 55 years, but occurs in 10%–15% of people between 65 and 75 years and 30%–60% of those over 85 years old. It typically involves the knee, wrist, ankle, shoulder and hip. Acute CPP inflammation can also affect axial skeletal structures. Risk factors for CPPD disease are shown in Box 26.45. Frequently, patients with CPPD disease have multiple joint chondrocalcinosis and a proportion present with chronic CPP crystal arthritis without a history of previous acute CPP crystal arthritis. The picture is typically an inflammatory poly-
arthritides superimposed on a background of OA – typically of the wrist, shoulder or knee (Fig. 26.29). Chronic CPP crystal arthritis can be mis-
taken for RA by the unwary, as MCP joints can be affected (usually just 2nd and 3rd, sparring the 4th and 5th) and low titre RF is a common incidental finding in old age. The prevalence of CPPD disease affecting the axial skeletal is unknown.
**26.45 The main risk factors for calcium pyrophosphate deposition disease**

**Common**
- Older age
- Osteoarthritis*
- Hyperparathyroidism (both primary and secondary)
- Hypovitaminosis-D (by causing secondary hyperparathyroidism)

**Rare**
- Familial factors*
- Haemochromatosis*
- Hypophosphatasia
- Hypomagnesaemia
- Hyperparathyroidism
- Wilson’s disease

*May be associated with structural damage to affected joints.

**Pathophysiology**

The underlying mechanisms of crystal deposition are poorly understood. Clinical studies have shown that CPP levels are raised in patients with CPPD disease, possibly due to over-production, but why this happens is unclear. In hypophosphatasia (see Box 26.73), the predisposing factor is thought to be impaired degradation of CPP due to deficiency of ALP. In OA, it is thought that a reduction in the amounts of proteoglycan and other natural inhibitors of crystal formation in the abnormal cartilage also predispose to crystal deposition (see Fig. 26.23).

**Clinical features**

The typical acute CPP crystal arthritis presentation is with a swollen tender joint that is warm and erythematous with a large effusion. Fever is common and the patient may appear confused and ill. The knee is most commonly affected, followed by the wrist, shoulder, ankle and elbow. Trigger factors include trauma, intercurrent illness, dehydration and surgery. Septic arthritis and gout are the main differential diagnoses.

Chronic CPP crystal arthritis can mimic RA, though joint involvement patterns are generally different (in chronic CPP crystal arthritis: wrists, MCP joints 2 and 3, ankles, shoulders). Affected joints usually show features of OA, with varying degrees of synovitis. Effusion and synovial thickening are usually most apparent at knees and wrists. Wrists involvement may result in carpal tunnel syndrome. Inflammatory changes can occur at entheses such as the gluteal tendon insertions at the greater trochanters and may involve tendons and the ligamentum flavum. Inflammation around the odontoid may occur secondary to CPP crystal deposition, leading to crowned dens syndrome; this presents clinically with neck and occipital neck pain (with neck rotation being the most severely affected movement). Severe damage and instability of knees, hips or shoulders can mimic a neuropathic joint.

**Investigations**

The pivotal investigation in diagnosing acute CPP crystal arthritis is joint aspiration, followed by examination of synovial fluid using compensated polarised microscopy to demonstrate CPP crystals (see Fig. 26.6B). The aspirated fluid is often turbid and may be uniformly blood-stained, reflecting the severity of inflammation. Since sepsis and acute CPP crystal arthritis can coexist, Gram stain and culture of the fluid should be performed to exclude sepsis, even if CPP crystals are identified in synovial fluid.

For diagnosing chronic CPP crystal arthritis and CPP axial skeletal disease, X-rays of the affected joints, carefully reviewed, may show evidence of calcification in hyaline cartilage and/or fibrocartilage or at periarticular entheses. Reviewing CT images if available (and windowed for bone), are often helpful in revealing CPP deposition in pelvic and spine structures. Screening for secondary causes (see Box 26.45) and metabolic risk factors should be undertaken in all cases of CPPD disease and abnormalities treated.

**Management**

In acute CPP crystal arthritis, ice packs, joint elevation and joint aspiration provides symptomatic relief. Once infection is excluded, intra-articular glucocorticoid can be injected. NSAIDs and colchicine (0.5–2 mg daily) are helpful, but must be used with caution in older patients. Chronic CPP crystal arthritis can respond to low-dose oral glucocorticoids, methotrexate and hydroxychloroquine. Colchicine long-term (0.5–1 mg daily) may play a role in preventing acute CPP inflammatory flare-ups. Little is known about the optimum drug management of chronic CPPD disease in the axial skeletal.

**Basic calcium phosphate deposition disease**

Basic calcium phosphate (BCP) deposition disease is caused by the deposition of hydroxyapatite or apatite crystals and other basic calcium phosphate salts (octacalcium phosphate, tricalcium phosphate) in soft tissues. The main affected sites are tendons, ligaments and hyaline cartilage in patients with degenerative disease, and skeletal muscle and subcutaneous tissues in connective tissue diseases.

**Pathophysiology**

Under normal circumstances, inhibitors of mineralisation, such as pyrophosphate and proteoglycans, prevent calcification of soft tissues. When these protective mechanisms break down, abnormal calcification occurs. There are many causes (Box 26.46). In most situations, calcification is of no consequence, but when the crystals are released an inflammatory reaction may be initiated, causing local pain and inflammation.

**Calcific periarthritis**

This occurs as the result of deposition of BCP in tendons, which provokes an acute inflammatory response. Commonly the supraspinatus tendon is affected (Fig. 26.29), but other sites may also be involved, including the tendons around the hip, feet and hands. The presentation is with acute pain, swelling and local tenderness that develops rapidly over 4–6 hours. The overlying skin may be hot and red, raising the possibility of infection. Attacks sometimes occur spontaneously, but can also be triggered by trauma. Modest systemic upset and fever are common. Tendon calcification may be seen on X-ray. If the affected joint or bursa is aspirated, inflammatory fluid containing many calcium-staining (alizarin red S) aggregates may be obtained. During an acute attack, there may be a neutrophilia with an elevation in ESR and CRP. Routine biochemistry
is normal. Treatment is with analgesics and NSAIDs. Attacks may also respond to a local injection of glucocorticoid. The condition usually resolves spontaneously over 1–3 weeks and this is often accompanied by dispersal and disappearance of calcific deposits on X-ray. Large deposits sometimes accumulate, causing limitation of joint movement, and may require surgical removal.

**Acute inflammatory arthritis**

Deposition of BCP occurs commonly in OA, both alone and in combination with CPP crystals, in which case it is referred to as mixed crystal deposition disease. An acute crystal-induced arthritis can occur, identical to pure acute CPP crystal arthritis.

**Milwaukee shoulder syndrome**

This is a rare syndrome, in which extensive deposition of BCP crystals in large joints is associated with progressive joint destruction. It is more common in women than in men. The onset is gradual, with joint pain, sometimes precipitated by injury or overuse. The disease progresses over a few months to cause severe pain and disability, associated with joint destruction. X-rays show joint space narrowing, osteophytes and calcification. Aspiration yields large volumes of relatively non-inflammatory fluid containing abundant BCP aggregates and often cartilage fragments. The differential diagnosis is end-stage osteonecrosis, chronic sepsis or neuropathic joint. There is no acute phase response and synovial fluid cultures are negative.

### Fibromyalgia

Fibromyalgia (FM) is a condition of generalised pain and consequent disability. It is frequently associated with medically unexplained symptoms in other systems. The prevalence in the UK and United States is about 2%–3%. Although FM can occur at any age, including adolescence, it increases in prevalence with age, to reach a peak of 7% in women aged over 70. There is a strong female predominance of around 10:1. Risk factors include life events that cause (unresolved) psychosocial distress relating to previous abuse, marital disharmony, alcoholism or illness in the family, poor sleep health, previous injury or assault and low income. FM arises in a variety of races and cultures. FM may co-exist with other inflammatory rheumatic diseases, including axSpA and SLE.

### Pathophysiology

The cause of FM is poorly understood, but two abnormalities that may be interrelated (Fig. 26.30), and have been consistently reported in affected patients, are disturbed, non-restorative sleep and pain sensitization, probably caused by abnormal central pain processing.

### Clinical features

The main presenting feature is widespread pain, which is often worst in the neck and back (Box 26.47). It is characteristically diffuse and unresponsive to analgesics and NSAIDs. Physiotherapy often makes FM pain worse. Fatigability, most prominent in the morning, is another major problem and disability is often marked. Although people can usually undertake self-care (such as eating, washing and dressing), they may be unable to perform tasks such as shopping or housework. They may

experience major performance difficulties at work, and may even stop working, because of pain and fatigue.

Examination is unremarkable, apart from the presence of hyperalgesia on moderate digital pressure (enough just to whiten the nail of the examiner) over multiple sites (Fig. 26.31).

**Investigations and management**

There are no abnormalities on routine blood tests or imaging, but it is important to screen for other conditions that could account for all or some of the patient’s symptoms (Box 26.48). Imaging is not generally recommended except to exclude other causes of pain if these are suspected clinically.

The aims of management are to educate the patient about the condition, address unresolved psychological issues, achieve pain control and improve sleep. Wherever possible, education should include the spouse, family or carer. It is conventional to acknowledge that the cause of FM is not fully understood, but the widespread pain does not reflect inflammation, tissue damage or disease. The model of a self-perpetuating cycle of poor sleep and pain (see Fig. 26.30) is a useful framework for problem-based management. Understanding the diagnosis can often help the patient come to terms with the symptoms. Repeat or drawn-out investigation may reinforce beliefs in occult serious pathology and should be avoided.

Low-dose amitriptyline (10–75 mg at night), with or without fluoxetine, may help by encouraging delta sleep and reducing spinal cord wind-up. Many people with FM, however, are intolerant of even small doses of amitriptyline. There is limited evidence for the use of tramadol, serotinin–noradrenaline (norepinephrine) re-uptake inhibitors (SNRIs) such as duloxetine, and the anticonvulsants pregabalin and gabapentin. A graded increase in aerobic exercise can improve well-being and sleep quality.

**Fig. 26.31 Typical tender points in fibromyalgia.**
The use of self-help strategies and a cognitive behavioural approach with relaxation techniques should be encouraged. Sublimated anxiety relating to distressing life events should be specifically explored with appropriate counselling. There are patient organisations that provide additional information and support. Although treatment may improve quality of life and ability to cope, most people remain symptomatic for many years.

**Bone and joint infections**

**Septic arthritis**

Septic arthritis is the most rapid and destructive joint disease. The incidence is 2–10 per 100,000 in the general population and 30–70 per 100,000 in those with pre-existing joint disease or joint replacement. Septic arthritis is associated with significant morbidity and still has a mortality of about 10% despite advances in antimicrobial therapy. The most important risk factor for mortality is increasing age.

**Pathogenesis**

Septic arthritis usually occurs as a result of haematogenous spread from infections of the skin or upper respiratory tract; infection from direct puncture wounds or secondary to joint aspiration is uncommon. Risk factors include increasing age, pre-existing joint disease (primarily RA), diabetes mellitus, advanced renal disease, immunosuppression (by drugs or disease) and intravenous drug misuse. In RA, the skin is a frequent portal of entry because of maceration of skin between the toes due to joint deformity and difficulties with foot hygiene caused by hand deformity. Box 26.49 describes the particular considerations in old age.

**Clinical features**

The usual presentation is with acute or subacute monoarthritis and fever. The joint is usually swollen, hot and red, with pain at rest and on movement. Although any joint can be affected, lower limb joints, such as the knee and hip, are most commonly targeted. Patients with pre-existing arthritis may present with multiple joint involvement.

The most common organism in adults is *Staphylococcus aureus*, particularly in patients with RA and diabetes, but infections with *S. haemolyticus* streptococci and Gram-negative bacilli are also frequent. Tuberculosis should always be considered where local population infection prevalence is high. Gonococcal infection can present with a migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. Gram-negative bacilli or group B, C and G streptococci are important causes among older adults and intravenous drug users. Less commonly, septic arthritis may be caused by group A streptococci, pneumococci, meningococci and *Haemophilus influenzae*. Arthritis may be a feature of Lyme disease caused by members of the *Borrelia* species of microorganisms. It is generally a late manifestation, which usually affects large joints. Brucellosis presents with an acute febrile illness, followed in some cases by the development of localised infection, which can result in arthritis, bursitis, osteomyelitis, sacroiliitis and paravertebral or psoas abscesses.

**Investigations**

The pivotal investigation is joint aspiration, but blood cultures should also be taken. The synovial fluid is usually turbid or blood-stained but may appear normal. If the joint is not readily accessible, aspiration should be performed under imaging guidance or in theatre. Prosthetic joints should only be aspirated in theatre to minimise the risk of introducing infection.

Synovial fluid should be sent for Gram stain and culture; cultures are positive in around 90% of cases, but the Gram stain is positive in only 50%. In contrast, synovial fluid culture is positive in only 30% of gonococcal infections, making it important to obtain concurrent cultures from the genital tract (positive in 70–90% of cases).

There is a leucocytosis with raised CRP in most patients, but these features may be absent in older or immunocompromised patients, or early in the disease course. Serial measurements of CRP are useful in following the response to treatment.

**Management**

The principles of management are summarised in Box 26.50. The patient should be admitted to hospital for pain relief and administration of parenteral antibiotics. Flucloxacinilin (2 g IV 4 times daily) is the antibiotic of first choice pending the results of cultures, since it will cover most *Staphylococcus* and *Streptococcus* infections. If there is reason to suspect meticillin-resistant *Staphylococcus aureus* (such as a known carrier), vancomycin should be used instead while awaiting cultures. If a Gram-negative infection is suspected, initial antibiotic treatment should cover Gram-negative bacilli as well as *Staphylococcus* and *Streptococcus*. *Cephalosporins* are a reasonable choice in this situation, but carry a high risk of *Clostridioides difficile* infection in those aged over 65; gentamicin is a good alternative.

**Box 26.50 Emergency management of suspected septic arthritis**

**Admit patient to hospital**

**Perform urgent investigations**

- Aspirate joint (use imaging guidance as needed). Send synovial fluid for Gram stain and culture
- Send blood for culture, routine biochemistry and haematology, including erythrocyte sedimentation rate and C-reactive protein
- Consider sending other samples (sputum, urine, wound swab) for culture, depending on patient history, to determine primary source of infection
- Consider sending serum sample (and later a paired sample) for *Neisseria* and *Brucella* serology

**Commence intravenous antibiotic**

- Flucloxacillin (2 g four times daily) to cover *S. aureus*
- If penicillin-allergic:
  - Clindamycin (450–600 mg four times daily in younger patients)
  - Intravenous vancomycin (1 g twice daily if age >65 years)
- If high risk of Gram-negative infection, in the immunocompromised and in IV drug users, add a 3rd generation cephalosporin
- When treating empirically before culture results are available, always seek local microbiology advice

**Relieve pain**

- Oral and/or intravenous analgesics or NSAID (caution in older patients)
- Consider local ice-packs

**Aspirate joint**

- Perform serial needle aspiration to dryness (1–3 times daily or as required)
- Consider arthroscopic drainage if needle aspiration difficult
- Consider synovial biopsy at arthroscopy for tissue for PCR analysis for TB

**Arrange physiotherapy**

- Early regular passive movement, progressing to active movements once pain controlled and effusion not re-accumulating

---

*Antibiotic choice should take local epidemiology and patient risk factors into account and be supported by local guidelines where available.*

**Image**

*Image description.*
to be considered as a cause in high prevalence areas. Osteomyelitis secondary to pyogenic organisms often results in a florid inflammatory response, with a greatly increased intraosseous pressure. If untreated, the condition may cause localised areas of osteonecrosis, leading to the development of a fragment of necrotic bone that is called a sequestrum. Eventual perforation of the cortex by pus stimulates local new bone formation (involution) in the periosteum, often leading to the development of sinuses that discharge through the skin.

**Clinical features**

The presentation is usually with localised bone pain and tenderness, often accompanied by malaise, night sweats and pyrexia. The adjacent joint may be painful to move and may develop a sterile effusion or secondary septic arthritis. Where the osteomyelitis is due to contiguous spread, there will be an overlying skin ulcer or wound, which often has necrotic tissue, purulent discharge and an offensive smell. In diabetic foot osteomyelitis, there may be no pain due to co-existent peripheral neuropathy.

**Investigations**

Patients suspected of having osteomyelitis should have an MRI, which is more sensitive than X-ray for detecting early changes. Where possible, cultures should be obtained by open or imaging-guided biopsy of the lesion. If tuberculosis is suspected, PCR-based analysis of synovial fluid or biopsy material should be considered. Evidence of osteopenia, localised osteolysis and osteonecrosis may be seen on X-ray. Blood cultures should be taken, which may also reveal the causative organism. Routine bloods typically show evidence of an acute phase response with a neutrophilia and raised ESR and CRP.

**Management**

Early recognition is critical as once osteomyelitis becomes established and chronic, it may prove very hard to eradicate with antibiotics alone. Ideally, antibiotics should not be started until the microbiological cause has been established. The principles are those followed for septic arthritis. An exception is in localised osteomyelitis of the toes and fingers, which can often be treated successfully with a prolonged course of oral antibiotics. Resection of the infected bone and subsequent reconstruction may be required. Complications of chronic osteomyelitis include secondary amyloidosis and skin malignancy at the margin of a discharging sinus (Marjolin’s ulcer).

**Discitis**

Discitis is an unusual condition in which there is infection of the intervertebral disc, often extending into the epidural space or paravertebral soft tissues. Staph. aureus is the most common pathogen. Risk factors include diabetes mellitus, immunodeficiency or immunosuppressive therapy, and intravenous drug use. The presentation is with back pain accompanied by fever, and an acute phase response with high ESR and CRP and a neutrophilia. If the diagnosis is suspected, an MRI should be performed and blood cultures taken. If blood cultures are negative, open or imaging-guided biopsy of the lesion should be performed to try to identify the organism responsible. Management is with supportive care and parenteral antibiotics followed by oral antibiotics, as described for osteomyelitis.

**Tuberculosis**

Tuberculosis (TB) of the musculoskeletal system is now rare in Europe and the United States, but remains common in sub-Saharan Africa and South Asia. It has been estimated to occur in about 1%–3% of patients with TB overall. In about 50% of cases, the spine is affected (Pott’s disease). Tuberculous osteomyelitis can also occur. Osteoarticular TB is thought to occur as the result of haematogenous spread from the site of primary infection, but a reactive arthritis (Poncet’s disease) can also occur in TB in the absence of direct infection. Peripheral arthritis tends
**Pathophysiology**

RA is a complex disease with both genetic and environmental components. The importance of genetic factors is demonstrated by higher concordance of RA in monozygotic (12%–15%) compared with dizygotic twins (3%) and an increased frequency of disease in first-degree relatives of patients. Genome-wide association studies have detected nearly 100 loci that are associated with the risk of developing RA. The strongest association is with variants in the HLA region and is determined by variations in three amino acids in the HLA-DRB1 molecule (positions 11, 71 and 74) and single variants in HLA-B (at position 9) and HLA-DRB1 (at position 9). The non-HLA loci generally lie within or close to genes involved in regulating the immune response. It is believed that RA occurs when an environmental stimulus, such as infection, triggers autoimmunity in a genetically susceptible host by modifying host proteins, through processes like citrullination, so that they become immunogenic. However, no single specific pathogen has been identified as a cause. An important environmental risk factor is cigarette smoking, which is also associated with more severe disease and reduced responsiveness to treatment. Remission may occur during pregnancy and sometimes RA first presents post partum. This is likely to be due to suppression of the immune response during pregnancy, but hormonal changes may also play a role.

The disease is characterised by infiltration of synovium with lymphocytes, plasma cells, dendritic cells and macrophages. There is evidence that CD4+ T and B cells play important roles in the pathogenesis of RA by interacting with other cells in the synovium, as illustrated in Figure 26.33. Lymphoid follicles form within the synovium in which T- and B-cell interactions occur, causing activation of T cells to produce cytokines and activation of B cells to produce autoantibodies, including RF and ACPA. Synovial macrophages are activated by TNF-α and interferon-gamma (IFN-γ), produced by T cells. The macrophages produce several pro-inflammatory cytokines, including TNF-α, IL-1 and IL-6, which act on synovial fibroblasts to produce further cytokines, setting up a positive feedback loop. The synovial fibroblasts proliferate, causing synovial hypertrophy and producing matrix metalloproteinases and the proteinase ADAMTS-5, which degrade soft tissues and cartilage. Prostaglandins and nitric oxide produced within inflamed synovium cause vasodilatation, resulting in swelling and pain. Systemic release of IL-6 triggers production of acute phase proteins by the liver. At the joint margin, the inflamed synovium (pannus) directly invades bone and cartilage to cause joint erosions. A key pathogenic factor in bone erosions and periarticular osteoporosis is osteoclast activation, stimulated by the production of M-CSF by synovial cells and RANKL by activated T cells (see Fig. 26.33). New blood-vessel formation (angiogenesis) occurs, causing the inflamed synovium to become highly vascular. Within these blood vessels, pro-inflammatory cytokines activate endothelial cells, which support recruitment of yet more leukocytes to perpetuate the inflammatory process.

Later, fibrous or bony ankylosis may occur. Muscles adjacent to inflamed joints atrophy and may be infiltrated with lymphocytes. This leads to progressive biomechanical joint dysfunction, which may further amplify joint destruction.

Rheumatoid nodules occur in patients who are RF- or ACPA-positive and primarily affect extensor tendons. They consist of a central area of fibrous material surrounded by a palisade of proliferating mononuclear cells. Granulomatous lesions may occur in the pleura, lung, pericardium and sclera.

**Clinical features**

The typical presentation is with pain, joint swelling and stiffness affecting the small joints of the hands, feet and wrists in a symmetrical fashion. Large joint involvement, systemic symptoms and extra-articular features may also occur. Clinical criteria for the diagnosis of RA are shown in Box 26.52.

Sometimes RA has an acute onset, with severe early morning stiffness, polyarthritis and pitting oedema. This occurs more commonly in old age. Another presentation is with proximal muscle stiffness mimicking polymyalgia rheumatica. Occasionally, the onset is palindromic, with relapsing and remitting episodes of pain, stiffness and swelling that last for only a few hours or days.

---

Rheumatoid arthritis (RA) is a common form of inflammatory arthritis, occurring throughout the world and in all ethnic groups. The prevalence of RA is approximately 0.8%–1.0% in Europe and South Asia, with a female-to-male ratio of 3:1. The prevalence is lower in South-east Asia (0.4%). The highest prevalence in the world is in Pima Indians (5%). It is a chronic disease characterised by a clinical course of exacerbations and remissions.
Examination typically reveals swelling and tenderness of the affected joints. Erythema is unusual and its presence suggests coexistent infection. Characteristic deformities may develop with long-standing uncontrolled disease, although these have become less common over recent years with more aggressive management. They include ulnar deviation of the fingers, ‘swan neck’ deformity, the boutonniere or ‘button hole’ deformity and a Z deformity of the thumb (Fig. 26.34). Dorsal subluxation of the ulna at the distal radio-ulnar joint may occur and contribute to rupture of the fourth and fifth extensor tendons. Triggering of fingers may occur because of nodules in the flexor tendon sheaths. Subluxation of the MTP joints of the feet may result in ‘cock-up’ toe deformities, causing pain on weight-bearing on the exposed MTP heads and the development of secondary adventitious bursae and callosities. In the hindfoot, a valgus deformity of the calcaneus may be observed as the result of damage to the posterior tibial tendon, then ankle and subtalar joints. This is often associated with loss of the longitudinal arch (flat foot) due to rupture of the tibialis posterior tendon. Popliteal (Baker’s) cysts may occur in patients with knee synovitis, in which synovial fluid communicates with the cyst, but is prevented from returning to the joint by a valve-like mechanism; this is not specific to RA. Rupture may be induced by knee flexion, leading to calf pain and swelling that may mimic a deep venous thrombosis (DVT).

**Systemic features**

Anorexia, weight loss and fatigue may occur throughout the disease course. Osteoporosis is a common complication and muscle-wasting may occur as the result of systemic inflammation and reduced activity. Extra-articular features are most common in patients with long-standing seropositive erosive disease, but may occasionally occur at presentation,

Nodules
Rheumatoid nodules occur almost exclusively in RF or ACPA-positive patients, usually in extensor tendons (Fig. 26.35). They are frequently asymptomatic, but some may be complicated by ulceration and secondary infection. Nodules are more common in smokers.

Vasculitis
This is uncommon, but may occur in seropositive patients. The presentation is with systemic symptoms, such as fatigue and fever and nailfold infarcts. Rarely, cutaneous ulceration, skin necrosis and mesenteric, renal or coronary artery occlusion may occur.

Ocular involvement
The most common symptom is dry eyes (keratoconjunctivitis sicca) due to secondary Sjögren syndrome. Scleritis and peripheral ulcerative keratits are uncommon, but are more serious and potentially sight-threatening complications that usually present with pain and redness. Clinical features and management are discussed in more detail in Chapter 30.

Serositis
Serositis is usually asymptomatic, but may present with pleural or pericardial pain and breathlessness. Pericardial effusion and constrictive pericarditis may rarely occur.

Cardiac involvement
Heart block, cardiomyopathy, coronary artery occlusion and aortic regurgitation have all been reported, but are rare. The risk of cardiovascular disease is increased due to a combination of conventional risk factors, such as high cholesterol, smoking, hypertension, reduced

physical activity, NSAIDs, glucocorticoids and the effects of inflammatory cytokines on vascular endothelium.

Pulmonary involvement
Pulmonary fibrosis may occur, but is often asymptomatic. There is some evidence that the risk of pulmonary fibrosis is increased by anti-TNF-α therapy, although it is uncertain whether this is causal or a marker of more severe disease in patients who require anti-TNF-α treatment.
Peripheral neuropathy

Entrapment neuropathies may result from compression by hypertrophied synovium or by joint subluxation. Median nerve compression is the most common and bilateral carpal tunnel syndrome can occur as a presenting feature of RA. Other syndromes include ulnar nerve compression at the elbow or wrist, compression of the lateral popliteal nerve at the head of the fibula, and tarsal tunnel syndrome (entrapment of the posterior tibial nerve in the flexor retinaculum), which causes burning, tingling and numbness in the distal sole and toes. Diffuse symmetrical peripheral neuropathy and mononeuritis multiplex may occur in patients with rheumatoid vasculitis.

Spinal cord compression

This rare complication is caused by compression of the spinal cord from subluxation of the cervical spine at the atlanto-axial joint or at a subaxial level (Fig. 26.36). Atlanto-axial subluxation is due to erosion of the transverse ligament posterior to the odontoid peg. It can lead to cord compression or sudden death following minor trauma or manipulation. It should be suspected in any RA patient who describes new onset of occipital headache, particularly if symptoms of paraesthesia or electric shock are present in the arms. The onset is often insidious, with subtle loss of function that may initially be attributed to active disease. Reflexes and power can be difficult to assess in patients with extensive joint disease and therefore sensory or upper motor signs are most important. Patients with evidence of spinal cord compression require urgent neurosurgical referral for stabilisation and fixation.

Other complications

Amyloidosis is a rare complication of long-standing disease that usually presents with nephrotic syndrome. Microcytic anaemia can occur due to iron deficiency resulting from NSAID-induced gastrointestinal blood loss, whereas normochromic, normocytic anaemia with thrombocytosis occurs in patients with active disease. Felty syndrome is a rare complication of seropositive RA in which splenomegaly occurs in combination with neutropenia and thrombocytopenia (Box 26.54). Localised or generalised lymphadenopathy can occur in patients with active disease, but persistent lymphadenopathy may indicate the development of lymphoma, which is more common in patients with long-standing RA.

**Investigations**

The diagnosis of RA is essentially clinical, but investigations are useful in confirming the diagnosis and assessing disease activity (Box 26.55). The ESR and CRP are usually raised, but normal results do not exclude the diagnosis, especially if only a few joints are involved. Tests for ACPA are positive in about 70% of cases and are highly specific for RA, occurring in many patients before clinical onset of the disease. Similarly, RF is also positive in about 70% of cases, most of whom also test positive for ACPA. RF is less specific than ACPA, however, and positive tests can occur in other diseases (see Box 26.7).

### 26.54 Felty syndrome

**Risk factors**
- Age of onset 50–70 years
- Female > male
- European > African ancestry
- Long-standing rheumatoid arthritis

**Common clinical features**
- Splenomegaly
- Lymphadenopathy
- Weight loss
- Skin pigmentation

**Laboratory findings**
- Normochromic, normocytic anaemia
- Neutropenia
- Abnormal liver function
- Deforming, but inactive disease
- Seropositive for rheumatoid factor
- Keratoconjunctivitis sicca
- Vasculitis, leg ulcers
- Recurrent infections
- Nodules
- Thrombocytopenia
- Impaired T- and B-cell immunity

### 26.55 Investigations and monitoring of rheumatoid arthritis

**To establish diagnosis**

- Clinical criteria
- Erythrocyte sedimentation rate and C-reactive protein
- Ultrasound or magnetic resonance imaging

**To monitor disease activity and drug efficacy**

- Pain (visual analogue scale)
- Early morning stiffness (minutes)
- Joint tenderness
- Rheumatoid factor and anti-citrullinated peptide antibodies
- Joint swelling
- DAS28 (Fig. 26.37)
- Erythrocyte sedimentation rate and C-reactive protein

**To monitor disease damage**

- X-rays
- Ultrasound
- Full blood count
- Chest X-ray
- Functional assessment
- Urea and creatinine
- Liver function tests

Ultrasound examination and MRI are not routinely required, but can be of value in patients with symptoms suggestive of RA where there is clinical uncertainty about the presence of synovitis. Plain X-rays of the hands, wrists and feet are usually normal in early RA, but periarticular osteoporosis and marginal joint erosions may be observed with more advanced disease. The main indication for an X-ray is in the assessment of patients with painful joints to determine whether significant structural damage has occurred. Patients who are suspected of having atlanto-axial disease should have lateral X-rays taken in flexion and extension, and an MRI. In those with suspected Baker’s cyst, ultrasound may be required to establish the diagnosis.

The Disease Activity Score in 28 joints (DAS28) is widely used to assess disease activity, response to treatment and need for biologic therapy. It involves counting the number of swollen and tender joints in the upper limbs and knees, and combining this with the ESR and the patient’s assessment of the activity of their arthritis on a visual analogue scale, where 0 indicates no symptoms and 100 the worst symptoms possible. Data are entered into a calculator to generate a numerical score. The higher the value, the more active the disease (Fig. 26.37).

**Management**

The treatment goal is to suppress inflammation, control symptoms, prevent joint damage and maintain function. This involves a combination of pharmacological and non-pharmacological therapies. When RA occurs in women of child-bearing age, additional considerations need to be taken into account and these are summarised in Box 26.56.

**Pharmacological therapy**

Prompt initiation of cDMARD therapy is indicated in all patients as this improves outcome. A variety of therapeutic regimens exist. A typical
Algorithm is shown in Figure 26.38. For example: on first diagnosis, prednisolone can be started in a dose of 30 mg daily gradually reducing in 5 mg increments every 2 weeks until therapy is withdrawn after about 12 weeks. At the same time, methotrexate (MTX) should be started in an initial dose of 15 mg weekly, along with folic acid 5 mg weekly, and escalated up to a maximum of 25 mg weekly, depending on the response. If the patient fails to respond adequately or dose-limiting toxicity occurs, then an additional cDMARD should be commenced in combination with MTX. A common combination is triple therapy, in which MTX, SSZ and HCQ are combined (see Fig. 26.39). Other cDMARD can be substituted or added, or subcutaneous MTX substituted for oral therapy, if the patient fails to respond fully. If disease activity remains high despite these measures, it is usual to progress to biologic or tsDMARD therapy. The most common used first-line biologic in RA is anti-TNF-α therapy, although several other options are available both in terms of tsDMARD (see Box 26.34) and other biologics (see Box 26.35). A reduction in biologic dose can be considered in patients who have been stable for 12 months or more on therapy, since it is possible to reduce the dose in up to 50% of patients without loss of therapeutic effect. Studies show that efficacy and durability of response to biologics is enhanced by co-treatment with MTX.

Disease flares can occur from time to time even in patients who are established on DMARD and biologic therapy. Transient flares can be dealt with by local joint or deep IM “depot” steroid injections or a short course of oral prednisolone, but if a sustained flare occurs, a change in DMARD and/or biologic should be considered.

**Fig. 26.37** Calculation of the Disease Activity Score 28 (DAS28).

*Erythrocyte sedimentation rate or C-reactive protein can be used for the calculation.

**Fig. 26.38** Algorithm for the management of rheumatoid arthritis.

**Non-pharmacological therapy**

Physiotherapy, occupational therapy and psychologist support are all important for RA patients. Liaison with social services may be appropriate and enhance the holistic support of patients whose lives are changed by the chronic disease. Patient-run charitable organisations can offer a wealth of education and support to RA patients and their families.

**Surgery**

Synovectomy can be helpful in joints that have failed to respond adequately to systemic therapy and intra-articular injections. Joint arthroplasty may be required where secondary OA evolves, but the need for this has diminished as the result of more aggressive medical management. Other surgical procedures that can be helpful are metatarsal osteotomies, ulna head excision with wrist synovectomy (and to prevent overlying extensor tendon rupture) and upper cervical spine fixation where there is progressive atlanto-axial subluxation. Joint fusion (wrist or triple hindfoot) can reduce pain where joint changes are severe/advanced (see Box 26.28).
Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term accepted by the international community for several forms of arthritis defined by the International League of Associations for Rheumatology 2001 criteria (Box 26.57). This includes juvenile forms of psoriatic arthritis (JPsA), rheumatoid arthritis (JRA) and more undifferentiated forms of inflammatory arthritis. The majority of patients with JIA have a phenotype that is distinct from adult inflammatory arthritis and includes a strong association with uveitis. JIA affects about 1:1000 children and young people up to 16 years of age – similar to the prevalence of diabetes (1:700). The annual incidence is approximately 1 per 10,000 children and young people.

Whereas joint restriction is attributed to damage in adults, in children it indicates inflammatory activity. Arthritis in children affects limb growth and has a negative effect on height and weight attainment. In young children, effective disease control can repair joint damage before puberty.

Oligoarthritis is the most common form of JIA, accounting for about 60% of cases. It is more common in females and tends to affect large joints in an asymmetrical pattern. There is an association with uveitis and many patients are ANA-positive. Polyarticular JIA is heterogeneous: some patients are RF and/or ACPA-positive, while others are negative for autoantibodies.

Systemic juvenile idiopathic arthritis (sJIA, formerly known as Still’s disease) is characterised by fever, rash, arthritis, hepatosplenomegaly and serositis in association with anaemia and a raised ESR and CRP. Autoantibody tests are negative. This form of JIA is associated with haemophagocytic syndrome (p. 939).

Many cases of enthesitis-related arthritis (ERA) are likely to be self-limiting forms of SpA. ERA can progress over time into a more obviously defined SpA.

**Investigations**

The ESR and CRP do not correlate well with the extent or severity of inflammation and may be normal. A very high ESR may indicate the presence of inflammatory bowel disease or very rarely leukaemia. Low haemoglobin is likely to be due to anaemia of chronic disease rather than iron deficiency. A positive ANA occurs in 40%–75% of cases of JIA and indicates an increased risk of eye disease. Ultrasound is the radiological investigation of choice to confirm synovitis or tenosynovitis. The false-negative rate is higher in foot and ankle disease than in other joints. Arthroscopy should be avoided unless a biopsy is required. Synovial fluid aspiration is essential if there is suspicion of infection.

**Management**

The key approach is to gain early rapid control of inflammation, minimise the adverse effects of treatment and support the general physical and mental health of the patient, and family, which requires full multidisciplinary team input. Standard therapy is MTX (subcutaneous MTX is typically used in the young child). Alternative treatment includes LEF, SSZ and HCQ. AZA and cyclosporin can be used to treat JIA with uveitis. MMF and tacrolimus are considered to have a specific role in treating uveitis alone. Drug combinations are not well studied in JIA. Where DMARDs fail, biologics (see Box 26.33), including anti-TNF-α, abatacept and tocilizumab, are effective in JIA, though precise indications and licensed use alone or with MTX do vary in parts of the world and according to local protocols and guidelines. Anakinra and canakinumab can be used to treat sJIA.

**Prognosis**

Suboptimal outcomes are associated with delayed diagnosis and referral to the specialist multidisciplinary team, inadequate disease control, presentation with uveitis, sJIA in males and poor engagement with services. Psychological support of affected children and their families is associated with improved outcome. Oligo-JIA often resolves at puberty. Polyarticular disease and sJIA remain active into adulthood in about 50% of cases. Common issues around the transition of adolescent patients into adulthood are shown in Box 26.58.

**Spondyloarthritides**

The spondyloarthritides comprise a group of related inflammatory diseases that show overlap in their clinical features and have a shared immunogenetic association with HLA-B27 (Box 26.59). The spectrum of spondyloarthritis (SpA) includes:

- **axial spondyloarthritis (axSpA)** comprising:
  - non-radiographic SpA (nr-axSpA)
  - radiographic axSpA (ankylosing spondylitis [AS])
- reactive SpA
- psoriatic arthritis
- arthritis with inflammatory bowel disease (enteropathic SpA).

In axSpA, the axial skeleton is predominantly affected. In contrast to RA, in SpAs there are frequent and notable non-syndial musculoskeletal lesions – mainly inflammatory in nature – of ligaments, tendons,

(ACPA = anti-citrullinated peptide antibody; ANA = antinuclear antibody; HLA = human leucocyte antigen; RA = rheumatoid arthritis; RF = rheumatoid factor)
periosteum and other bone lesions. A hallmark lesion of SpAs is enthesitis, which is inflammation at the site of a ligament or tendon insertion into bone. Dactylitis, inflammation of a whole finger or toe, may also occur (see Fig. 26.44).

It has been estimated that about 1% of the adult population in the United States may have a SpA (about 2.7 million). There is a striking association with HLA-B27, particularly for AS (>95%). For AS there is a male-to-female ratio of about 3:1. In Europe, more than 90% of those affected are HLA-B27-positive (HLA-B27 population prevalence in those of European origin is 9%). The overall prevalence of AS is below 0.5% in most populations. Additionally, SpAs are thought to arise as the result of an aberrant host response to infection and abnormal mucosal immunity primarily mediated through increased production of IL-23, which in turn causes activation of Th17 lymphocytes that produce IL-17, TNF-α and other inflammatory cytokines. In some situations, a triggering organism can be identified, as in reactive arthritis following bacterial dysentery or chlamydial urethritis, but in others the environmental trigger remains obscure. Familial clustering not only is common to the specific condition occurring in the proband, but also may extend to other diseases in the SpA group.

**Axial spondyloarthritis**

Axial spondyloarthritis (axSpA) is the diagnostic term that includes patients with non-radiographic axial SpA (nr-axSpA) and ankylosing spondylitis (AS, also termed radiographic axSpA. Box 26.60). Inflammatory changes in the axial skeleton (such as spondilits, see Fig. 26.40) are characteristic of axSpA and are visualised by MRI. Radiographic alterations, such as new bone formation with syndesmophytes and ankylosis, develop later in the course of the disease and, by definition, are not present in patients with nr-axSpA. A diagnosis of AS (radiographic axSpA), which requires evidence of these radiographic changes on X-ray, may only be applied many years after a patient’s symptoms started. It is important to recognise that not all patients with nr-axSpA will go on to develop AS.

**Pathophysiology**

Axial SpA arises from an interaction between environmental pathogens and the host immune system in genetically susceptible individuals. Increased faecal carriage of Klebsiella aerogenes has been reported in patients with AS and may relate to exacerbation of both joint and eye disease. There is increasing evidence that axSpA is due to an abnormal host response to the intestinal microbiota with involvement of Th17 cells, which have a key role in mucosal immunity. This leads to production of various inflammatory cytokines, including IL-23, IL-17 and TNF-α, which play vital roles in the pathogenesis of enthesitis and other inflammatory lesions (Fig. 26.39).

There is a strong association between axSpA and carriage of the major histocompatibility complex (MHC) class I molecule HLA-B27. This is particularly striking in patients defined as having AS, more than 95% of whom are positive for HLA-B27. Other susceptibility genes also implicated in susceptibility to AS include ERAP-1 (an endoplasmic reticulum protein with a role facilitating intracellular antigen processing and binding with its presenting MHC molecule HLA-B27), the IL-23 receptor and downstream signalling molecules involved in directing Th17 cell responses, such as ST473 (see Fig. 4.3). The HLA-B27 molecule itself is implicated through its antigen-presenting function or because of its propensity to form homodimers that activate leucocytes. HLA-B27 molecules may also misfold, causing increased endoplasmic reticulum stress. This could lead to inflammatory cytokine release by macrophages and dendritic cells, thus triggering inflammatory disease.

**Clinical features**

The cardinal feature of axSpA is inflammatory back pain and early morning stiffness, with low back pain radiating to the buttocks or posterior thighs if the sacroiliac joints are involved. Symptoms are exacerbated by inactivity and relieved by movement. Musculoskeletal symptoms may be prominent at entheses, may be episodic and, if persistent, can present as widespread pain and be mistaken for fibromyalgia. Fatigue is common. A history of psoriasis (current, previous or in a first-degree relative) and inflammatory bowel symptoms (current or previous) are important clues. Physical signs include a reduced range of lumbar spine movements in all directions, pain on sacroiliac stressing and a high entheses index. Entheses that are typically affected include Achilles’ insertion, plantar fascia origin, patellar ligament entheses, gluteus medius insertion at the greater trochanter and tendon attachments at humeral epicondyles. Acute anterior uveitis is the most common extra-articular feature, which occasionally precedes joint disease. The extent of extra-articular features are shown in Box 26.61.

A number of validated clinical questionnaires, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Functional Index (BASI) and Ankylosing Spondylitis Disease Activity Score (ASDAS-CRP), can be used to assess disease activity and functional status.

Spinal fusion can develop as AS progresses, but it does so over many years, varies in its extent and in most cases does not cause a gross flexion deformity. However, a few patients develop marked kyphosis of the dorsal and cervical spine that may interfere with forward vision. This may prove incapacitating, especially when associated with fixed flexion contractures of hips or knees. Osteoporosis is a common complication, particularly of the spine, leading to an increased risk of vertebral fracture.

**Investigations**

The diagnosis of axSpA is aided by ultrasound or MRI of entheses, or by MRI of the sacroiliac joints and spine (Fig. 26.40). Other findings may include raised ESR and CRP (although these can be normal), anaemia...
**Fig. 26.39** Pathophysiology of axial spondyloarthritis. In genetically susceptible individuals, it is thought that bacterial components penetrate the mucosal barrier to activate macrophages and dendritic cells in the intestinal submucosa. These cells produce increased amounts of interleukin (IL)-23, which activate Th17 cells resulting in production of IL-17, tumour necrosis factor (TNF-α) and other inflammatory mediators. IL-17 has a pivotal role in driving inflammation, causing sacroiliitis and enthesitis. Production of IL-22 by T cells is thought to be involved in causing the new bone formation that occurs in of axial spondyloarthritis. (RANKL = receptor activator of nuclear factor kappa B ligand)

**26.61 Extra-articular features of axial spondyloarthritis**
- Fatigue, anaemia
- Anterior uveitis (25%) and sterile urethritis
- Inflammatory bowel disease (in up to 50%)
- Osteoporosis
- Osteoproliferation and osteosclerosis
- Cardiovascular disease (aortic valve disease 20%)
- Amyloidosis (rare)
- Atypical upper lobe pulmonary fibrosis (very rare)

**Fig. 26.40** Magnetic resonance imaging appearances in sacroiliitis. Coronal MRI short T1 inversion recovery (STIR) sequence showing bilateral sacroiliitis in axial spondyloarthritis. Bone marrow oedema (circles) is present around both sacroiliac joints, which show irregularities due to erosions (arrows).

and positive HLA-B27. Faecal calprotectin is a useful screening test for associated inflammatory bowel disease.

By definition, abnormalities are not seen in X-rays in nr-axSpA. In AS, X-rays of the sacroiliac joint show irregularity and loss of cortical margins, widening of the joint space and subsequently sclerosis, joint space narrowing and fusion. Lateral thoracolumbar spine X-rays may show anterior ‘squaring’ of vertebrae due to erosion and sclerosis of the anterior corners and periostitis of the waist. Bridging syndesmophytes may also be seen. These are areas of calcification that follow the outermost fibres of the annulus (Fig. 26.41). In advanced disease, ossification of the anterior longitudinal ligament and facet joint fusion may also be visible. The combination of these features may result in the typical ‘bamboo’ spine (Fig. 26.42). Erode changes may be seen in the symphysis pubis, ischial tuberosities and peripheral joints. Osteoporosis is common and vertebral fractures may occur. Atlanto-axial dislocation can arise as a late feature. MRI is more sensitive for detection of early sacroiliitis than X-rays (see Fig. 26.40) and can also detect inflammatory changes in the lumbar spine. DXA scanning or vertebral quantitative CT is important as part of a fragility fracture assessment.

**Management**

Patient education, NSAID use (optimally, once daily or slow release taken at bedtime) and physical therapy are key interventions at the outset. For severe and/or persistent peripheral joint involvement, both SSZ and MTX are reasonable therapy choices. These medications have no impact on spinal symptoms or disease progression. In patients who fail to respond adequately or who cannot tolerate NSAIDs, progression to biologic therapy with either TNF-α or IL-17A inhibitors should be considered. Anti-TNF therapy is effective for both the axial and peripheral lesions of axSpA, but it is as yet unclear whether anti-TNF-α therapy modifies the natural history of the disease.

Local glucocorticoid injections can be useful for persistent plantar fasciitis, other enthesopathies and peripheral arthritis. Oral glucocorticoids may be required for acute uveitis, but do not help spinal disease. Severe hip, knee or shoulder arthritis with secondary OA may require
Reactive arthritis

Reactive (spondylo)arthritis (ReA) is a ‘reaction’ to a number of bacterial triggers with clinical features in keeping with all SpA conditions. The known triggers are *Chlamydia*, *Campylobacter*, *Salmonella*, *Shigella* and *Yersinia*. Notably, non-SpA-related reactive arthritis can occur following infection with many viruses, *Mycoplasma*, *Borrelia*, streptococci and mycobacteria, including *M. leprae*, which causes leprosy (Hansen’s disease); however, the ‘reaction’ in these instances consists typically of myceralalgias, is not associated with HLA-B27 and is generally not chronic. The arthritis associated with rheumatic fever is also an example of a reactive arthritis that is not associated with HLA-B27.

Sexually acquired reactive arthritis (SARA) is predominantly a disease of young men, with a male preponderance of 15:1. This may reflect a difficulty in diagnosing the condition in young women, in whom *Chlamydia* infection is often asymptomatic and hard to detect in practical terms. Between 1% and 2% of patients with non-specific urethritis seen at genitourinary medicine clinics have SARA. The syndrome of chlamydial urethritis, conjunctivitis and reactive arthritis was formerly known as Reiter’s disease.

With enteric triggering infections (enteropathic ReA), HLA-B27 may predict the reactive arthritis and its severity, though the condition occurs in HLA-B27-negative people. The incidence of specific triggering infections causing ReA around the world varies, depending on the epidemiology of the infection and prevalence of HLA-B27 in the local population.

Clinical features

The onset is typically acute, with an inflammatory enthesitis, oligoarthritis, sacroiliitis and/or spinal inflammation. Lower limb joints and entheses are predominantly affected. In all types of ReA, there may be considerable systemic disturbance, with fever and weight loss. Achilles insertional enthesitis/tendonitis or plantar fasciitis may also be present. The first attack of arthritis is usually self-limiting, but recurrent or chronic arthritis can develop and about 10% of patients will still have active disease 20 years after the initial presentation. Low back pain and stiffness due to enthesitis and osteitis are common and 15%–20% of patients develop sacroiliitis. Many extra-articular features in ReA involve the skin, especially in SARA:

- circinate balanitis, which starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give a circular pattern
• keratoderma blennorrhagica, which begins as discrete waxy, yellow-brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques on the palms and soles of the feet
• pustular psoriasis
• nail dystrophy with subungual hyperkeratosis
• mouth ulcers
• conjunctivitis
• uveitis, which is rare with the first attack, but arises in 30% of patients with recurring or chronic arthritis.

Other complications in ReA are very rare but include aortic incompetence, conduction defects, pleuro-pericarditis, peripheral neuropathy, seizures and meningoencephalitis.

Investigations

The diagnosis is usually made clinically, but joint aspiration may be required to exclude crystal arthritis and arthritic infection. ESR and CRP are raised. High vaginal swabs may reveal Chlamydia on culture. Except for post-Salmonella arthritis, stool cultures are usually negative by the time the arthritis presents, but serology may help confirm previous dysentry, RF, ACPA and ANA are negative.

In chronic or recurrent disease, X-rays show periarticular osteoporosis; proliferative erosions, notably at entheses; periostitis, especially of metatarsals, phalanges and pelvis; and large, ‘fluffy’ calcaneal spurs. In contrast to AS, radiographic sacroilitis is often asymmetrical and sometimes unilateral, and syndesmophytes are predominantly coarse and asymmetrical, often extending beyond the contours of the annulus (‘non-marginal’) (see Fig. 26.41B). Radiographic changes in the peripheral joints and spine are identical to those seen in psoriasis.

Management

Acute ReA should be treated with rest, NSAIDs and analgesics. Intra-articular or systemic glucocorticoids may be required in patients with severe monoarticular synovitis or polyarticular disease, respectively. There is no convincing evidence for the use of antibiotics unless a triggering infection is identified. If chlamydial arthritis is diagnosed, it should be treated empirically with a short course of doxycycline or a single dose of azithromycin. Treatment with DMARDs (usually SSZ or MTX) should be considered for patients with persistent marked symptoms, recurrent arthritis or severe keratoderma blennorrhagica. Anterior uveitis is a medical emergency requiring topical, subconjunctival or systemic glucocorticoids. For DMARD-recalcitrant cases, anti-TNF-α therapy should be considered.

Psoriatic arthritis

Based on data from the UK and Denmark, the estimated population prevalence of psoriatic arthritis (PsA) from registry and coding data is approximately 0.2%. It is likely the true prevalence is considerably higher, but this has not been extensively studied. The prevalence of PsA in psoriasis patients is variable, based on clinical assessment, but may be up to 40%. Early PsA may present as axSpA. The onset is usually between 25 and 40 years of age, but juvenile forms exist. Occasionally, the arthritis and psoriasis develop synchronously, but the onset of musculoskeletal and skin disease is frequently separated by many years. Classification of PsA requires key assessments of family history and screening for enthesitis (Box 26.62).

Pathophysiology

Genetic factors have an important role in PsA and family studies have suggested that heritability may exceed 80%. Variants in the HLA-B and HLA-C genes are the strongest genetic risk factors, but more than 30 other variants also play a part. Carriage of the HLA B27 allele in those with PsA of European descent is about 20% as compared with the background rate of 9%. Many of these variants overlap with those implicated in psoriasis, where there are more than 40 susceptibility loci. These lie within or close to genes in the IL-12, IL-23 and nuclear factor kappa B (NFκB) signalling pathways. It is thought that an environmental factor, probably infectious in nature, triggers the disease in genetically susceptible individuals, leading to immune activation involving dendritic cells and T cells. CD8+ T cells (which recognise antigen presented in the context of HLA class I) are more abundant than CD4+ T cells within the joint, which is in keeping with the genetic association between PsA and HLA-C and B variants. There is increasing evidence that the IL-23/IL-17 pathway plays a pivotal role in PsA. It is thought that the triggering stimulus causes over-production of IL-23 by dendritic cells, which in turn promotes differentiation and activation of Th17 cells that produce the pro-inflammatory cytokine IL-17. This, along with Th1 cytokines like IFN-γ and TNF-α, acts on macrophages and tissue-resident stromal cells at entheses, in bone and within the joint to produce additional pro-inflammatory cytokines and other mediators, which contribute to inflammation and tissue damage, as shown in Figure 26.43.

Clinical features

The presentation is with pain and stiffness affecting joints, tendons, spine and entheses. Joints are typically not swollen; however, several patterns of joint involvement are recognised (see below), including an oligoarticular form. These patterns are not mutually exclusive. Marked variation in disease patterns exists, including a disease course of intermittent exacerbation and remission. Destructive arthritis and disability are uncommon, except in the case of arthritis mutilans. Though both psoriasis and PsA are associated with obesity, it is not clear if the latter plays a role in aetopathogenesis.

Asymmetrical inflammatory mono-/oligoarthritis

This often presents abruptly with a combination of synovitis and adjacent periarticular inflammation. It occurs most characteristically in the hands and feet, when synovitis of a finger or toe is coupled with tenosynovitis, enthesitis and inflammation of intervening tissue to give a ‘sausage digit’ or dactylitis (Fig. 26.44A). Large joints, such as the knee and ankle, may also be involved, sometimes with very large effusions.

Symmetrical polyarthritis

This accounts for about 25% of cases. It predominates in women and may resemble RA, with symmetrical involvement of small and large joints in both upper and lower limbs. Nodules and other extra-articular features of RA are absent and arthritis is generally less extensive and more benign.

Distal interphalangeal joint arthritis

This is quite a common pattern. It can be difficult to distinguish from inflammatory generalised OA, but in PsA psoriatic nail disease is usually present (Fig. 26.44B).

Psoriatic spondylitis

This type presents with inflammatory back or neck pain and stiffness. Any structure in the spine can be involved, including intervertebral discs, entheses and facet joints. It may occur alone or with any of the other clinical patterns and is typically unilateral or asymmetric in severity.
Fig. 26.43 Pathogenesis of psoriatic arthritis. As in the case of axSpA, the IL-23/IL-17 axis is thought to play a key role in PsA. Some of the cytokines and cellular interactions important in psoriatic arthritis are also shown. (ADAMTS-5 = aggrecanase; IFN = interferon; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; TNF = tumour necrosis factor; RANKL = receptor activator of nuclear factor kappa B ligand)

Arthritis mutilans
This is a deforming erosive arthritis targeting the fingers and toes; it occurs in 5% of cases of PsA. Prominent cartilage and bone destruction results in marked digital instability. The encasing skin appears invaginated and “telescoped” (“main en lorgnette”) and the finger can be pulled back to its original length.

Enthesitis-predominant
This form of disease presents with pain and stiffness at the insertion sites of tendons and ligaments into bone (enthesitis). Symptoms can be extensive or localised. Patients often report muscle stiffness or achy. Typically affected entheses include Achilles tendon insertions, plantar fascia origins, patellar ligament insertions, hip abductor complex insertion at lateral femoral condyle, gluteus medius insertion at greater trochanter, humeral epicondyle tendon insertions, deltoid origin at acromial edge, intercostal muscle insertions at ribs, and pelvic ligament insertions. This form of PsA can be mistaken for fibromyalgia by the unwary.

Nail changes
Nail changes include pitting, onycholysis, subungual hyperkeratosis and horizontal ridging, which are found in 85% of patients with PsA and can occur in the absence of skin disease. The characteristic rash of psoriasis may be widespread, or confined to the scalp, natal cleft, umbilicus and genitals, or in areas where there are frictional skin effects (e.g. from clothing) where it is easily overlooked. Obtaining a history of psoriasis in a first-degree relative can be tricky but is important, given that a positive response contributes to making a diagnosis. Psoriasis and PsA may be discordant in the same individual, with onset of features sometimes years apart. The absence of psoriasis, or history of it, does not preclude a diagnosis of PsA (see Box 26.62).
Investigations

The diagnosis is made on clinical grounds. Autoantibodies are usually negative, though low-dose RF, ACPA and ANA can be detected, and acute phase reactants, such as ESR and CRP, are raised in only a proportion of patients with active disease. X-rays may be normal or show juxta-articular osteoporosis or erosive change with joint space narrowing. Features that favour PsA over RA include the characteristic distribution (see Fig. 26.10) of erosions with osteoporosis, absence of periarticular osteoporosis and osteosclerosis. Imaging of the axial skeleton, in advanced disease, can show coarse, asymmetrical, non-marginal syndesmophytes, juxta-facet joint osteoporosis and sacroiliitis. MRI and ultrasound with power Doppler are increasingly employed to detect synovial inflammation and inflammation at the entheses.

Management

Patient education to understand the breadth, episodic nature and variability of disease is important. Weight loss may play a therapeutic role to limit clinical impact. Therapy with NSAIDs and analgesics may be sufficient to manage symptoms in mild disease. Intra-articular glucocorticoid injections can control isolated synovitis or enthesitis. Splints and prolonged rest should be avoided because of the tendency to fibrous and bony ankylosis. Patients with spondylitis should be prescribed the same exercise and posture regime as in axSpA. Therapy with cDMARDs should be considered for polyarthritides or synovitis unresponsive to conservative treatment. MTX is the drug of first choice and is also effective for skin disease. Other cDMARDs may also be helpful, including SSZ, ciclosporin and LEF. Particular attention should be paid to monitoring liver function in patients treated with cDMARDs, since abnormalities are common in PsA. HCQ is not generally used in PsA, but can be tried if other options are unsuitable. Anti-TNF-α should be considered for individuals with active synovitis who respond inadequately to cDMARDs, and treatment is effective for both PsA and psoriasis. Ustekinumab, a monoclonal antibody that binds to and neutralises the p40 subunit of IL-12 and IL-23, improves joint, dactylitis and enthesitis lesions in PsA, as does guselkumab which is a specific inhibitor of IL-23. Secukinumab and ixekizumab, monoclonal antibodies that target IL-17, have similar or even greater efficacy than TNF-α inhibitors in PsA. Apremilast is effective in PsA when cDMARD therapy fails, but is less efficacious than biologic treatments.

Enteropathic (spondylo)arthritis

The overall prevalence of inflammatory musculoskeletal disease in inflammatory bowel diseases (IBDs: Crohn's disease and ulcerative colitis) is not well known, as studies have not adequately assessed enthesitis and osteitis lesions, but the musculoskeletal manifestations are in keeping with a SpA phenotype. Involvement of the peripheral joints is seen in about 20% of IBD patients. Oligoarticular disease predominantly affects the large lower limb joints (knees, ankles and hips). Evidence of sacroiliitis can also be detected by imaging in a proportion of patients with IBD. Imaging evidence of sacroiliitis is present in about 15%–20% of IBD patients. Crohn's disease of the colon is a typical lesion. In Crohn's disease, more than in colitis, the arthritis usually coincides with exacerbations of the underlying bowel disease and the arthritis improves with effective treatment of the bowel disease. There is some suggestion that the severity and onset of inflammatory musculoskeletal symptoms can vary in association with changes in the integrity of the ileocaecal valve, raising the possibility that changes in gut flora may act as triggers for the associated SpA.

NSAIDs are best avoided, since they can exacerbate IBD. Instead, judicious use of glucocorticoids, SSZ and MTX may be considered. Liaison is necessary between gastroenterologist and rheumatologist with regard to choice of therapy. Anti-TNF-α therapy is effective in enteropathic arthritis, but etanercept should be avoided as it has no efficacy in IBD. Anti-IL-17A therapy should be avoided as it can trigger flares of IBD. Tofacitinib, while not specifically licensed for enteropathic arthritis, is efficacious in ulcerative colitis and might be a further treatment option. When musculoskeletal symptoms worsen despite anti-TNF-α therapy, it is wise to exclude small intestinal bacterial overgrowth as a triggering cause.

Autoimmune connective tissue diseases

Autoimmune connective tissue diseases (AICTDs) share many clinical features and are characterised by dysregulation of immune responses, with autoantibody production that is often directed at components of the cell nucleus, and tissue damage.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a rare disease with a prevalence that ranges from about 0.03% in people of European descent to 0.2% in people of African Caribbean origin. Some 90% of affected patients are female and the peak age at onset is between 20 and 30 years. SLE is associated with considerable morbidity and a fivefold increase in mortality compared to age- and gender-matched controls, mainly because of an increased risk of premature cardiovascular disease.

Pathophysiology

The cause of SLE is incompletely understood. Genetic factors play a role and the strongest region of association lies with alleles in the HLA-DR and DQ regions. However, approximately 100 other susceptibility loci, which lie within or close to genes involved in the immune response, have also been identified by genome-wide association studies. The overall heritability of SLE has been estimated to be about 40%–60%, illustrating the importance of environmental influences, although the nature of these are unclear. In a few instances, SLE is associated with inherited mutations in complement components C1q, C2 and C4, in the immunoglobulin receptor FCyRIIb and in the DNA exonuclease T3EX. From an immunological standpoint, the characteristic feature of SLE is autoantibody production. These autoantibodies have specificity for a wide range of targets, but many are directed against antigens present within the cell or within the nucleus. This has led to the hypothesis that SLE may occur because of defects in apoptosis or in the clearance of apoptotic cells, which causes inappropriate exposure of intracellular antigens on the cell surface, leading to polyclonal B- and T-cell activation, and autoantibody production. In support of this, environmental factors that cause flares of SLE, such as ultraviolet light and infections, increase oxidative stress and cause cell damage. Whatever the underlying cause, autoantibody production and immune complex formation are thought to be important mechanisms of tissue damage in active SLE, leading to vasculitis and organ damage.

Clinical features

Symptoms such as fever, weight loss and mild lymphadenopathy may occur during flares of disease activity, whereas others such as fatigue and low-grade joint pains can be constant and not particularly associated with active inflammatory disease.

Arthritis

Arthralgia is a common symptom, occurring in 90% of patients, and is often associated with early morning stiffness. Tenosynovitis may also occur, but clinically apparent synovitis with joint swelling is unusual. Joint deformities may arise (Jaccoud's arthropathy) as the result of tendon damage, but joint erosions are not a feature.

Raynaud's phenomenon

Raynaud's phenomenon (RP) is characterised by vasoconstriction of the small vessels of the hand and feet in response to cold, leading to pallor followed by cyanosis of the affected digits followed by vasodilatation causing the affected digits to turn red. This is a common feature of SLE and may antedate other symptoms by months or years. Raynaud's
phenomenon associated with SLE and other AICTDs (secondary RP) needs to be differentiated from primary RP, which is a benign disorder that is common in the general population (up to 5%). Features of secondary RP include age at onset of over 25 years, other features of AICTD, absence of a family history of RP, severity of symptoms, presence of digital ulceration (Fig. 26.45) and male gender. Examination of capillary nail-fold loops using an ophthalmoscope (with oil placed on the skin) can show loss of the normal loop pattern, with capillary ‘fallout’ and dilatation and branching of loops; these features support a diagnosis of secondary RP, but can be observed in severe primary RP.

Skin

The skin is commonly involved in SLE and many eruptions are precipitated by exposure to ultraviolet light. The main types of skin involvement are:

- The classic malar facial rash (up to 20% of patients). This is erythematous, raised and painful or itchy, and occurs over the cheeks with sparing of the nasolabial folds (Fig. 26.46). Rosacea may mimic this rash.
- A discoid rash characterised by hyperkeratosis and follicular plugging, with scarring alopecia if it occurs on the scalp.
- Diffuse, usually non-scarring alopecia, which may also occur with active disease.
- Urticarial eruptions.

Kidney

Renal involvement is one of the main determinants of prognosis and regular monitoring of urinalysis and blood pressure is essential. The typical renal lesion is a proliferative glomerulonephritis, characterised by heavy haematuria, proteinuria and casts on urine microscopy.

Cardiovascular

The most common manifestation is pericarditis. Myocarditis and Libman–Sacks endocarditis can also occur. The endocarditis is due to accumulation on the heart valves of sterile fibrin-containing vegetations, which is thought to be a manifestation of hypercoagulability associated with antiphospholipid antibodies. The risk of atherosclerosis is greatly increased, as is the risk of stroke and myocardial infarction. This is thought to be multifactorial due to the adverse effects of inflammation on the endothelium, chronic glucocorticoid therapy and the procoagulant effects of antiphospholipid antibodies.

Lung

Lung involvement is common and most frequently manifests as pleuritic pain (serositis) or pleural effusion. Other features include pneumonitis, atelectasis, reduced lung volume and pulmonary fibrosis. The risk of thromboembolism is increased, especially in patients with antiphospholipid antibodies.

Neurological

Fatigue, headache and poor concentration are common and often occur in the absence of laboratory evidence of active disease. More specific features of cerebral SLE include visual hallucinations, chorea, organic psychosis, transverse myelitis and lymphocytic meningitis.

Haematological

Neutropenia, lymphopenia, thrombocytopenia and haemolytic anaemia may occur, due to antibody-mediated destruction of peripheral blood cells. The degree of lymphopenia can be a guide to disease activity.

Gastrointestinal

Mouth ulcers may occur and can be painful. Peritoneal serositis can cause acute pain. Mesenteric vasculitis is a serious complication, which can present with abdominal pain, bowel infarction or perforation. Hepatitis is a recognised, though rare, feature.

Paediatric disease

Renal disease and cutaneous manifestations are more frequent in juvenile-onset SLE compared to disease in adults. Similarly, there is
subsequently a higher incidence of renal disease, malar rash, Raynaud’s phenomenon, cutaneous vasculitis and neuropsychiatric manifestations than in adults.

**Investigations**

The diagnosis is based on a combination of clinical features and laboratory abnormalities. To fulfill the classification criteria for SLE, at least 4 of the 11 factors shown in Box 26.63 must be present or have occurred in the past. Checking of ANAs, antibodies to ENAs and complement, routine haematology, biochemistry and urinalysis are mandatory. Patients with active SLE are almost always positive for ANA. ANA-negative SLE can occur, but this is rare and in such cases antibodies to the ENA Ro or antiphospholipid antibodies are present. Anti-dsDNA antibodies are positive in most patients and are quite specific for SLE. Serum levels of C3 may be low in active SLE due to complement consumption, but in some people low C3 and C4 can also be caused by inherited deficiencies in C1, C2, or C4, all of which predispose to SLE. Studies of other family members can help to differentiate inherited deficiencies from complement consumption. A raised ESP, leucopenia and lymphopenia are typical of active SLE, and this may be accompanied by anaemia, haemolytic anaemia and thrombocytopenia. CRP is often normal in active SLE and presence of an elevated CRP in SLE raises the possibility of either sepsis, or co-existing infection.

**Management**

The therapeutic goals are to educate the patient about the nature of the illness, to control symptoms and to prevent organ damage and maintain normal function. Patients should be advised to avoid sun and ultraviolet light exposure and to employ sun blocks (sun protection factor 25–50).

Mild to moderate disease

Patients with mild disease restricted to skin and joints can sometimes be managed with analgesics, NSAIDs and HCQ. Frequently, however, glucocorticoids are also necessary (prednisolone 5–20 mg/day), often in combination with immunosuppressants such as MTX, azathioprine or mycophenolate mofetil (MMF). Increased doses of glucocorticoids may be required for flares in activity or complications such as pleurisy or pericarditis. The monoclonal antibody belimumab has been shown to be effective in patients with active SLE who have responded inadequately to standard treatment. Fatigue may be problematic, but there is some evidence that low intensity regular aerobic exercise can be helpful. Poor sleep hygiene should be addressed to try to combat this symptom.

**Severe and life-threatening disease**

High-dose glucocorticoids and immunosuppressants are required for the treatment of renal, CNS and cardiac involvement. A commonly used regimen is pulsed methylprednisolone (10 mg/kg IV) plus cyclophosphamide (15 mg/kg IV), repeated at 2–3-weekly intervals for six cycles. Cyclophosphamide may cause haemorrhagic cystitis, but the risk can be minimised by good hydration and co-prescription of mesna (2-mercaptopethane sulfonate), which binds its urotoxic metabolites. Because of the risk of azoospermia and premature menopause, sperm or oocyte collection and storage need to be considered prior to treatment with cyclophosphamide.

MMF has been used successfully with high-dose glucocorticoids for renal involvement with results similar to those of pulsed cyclophosphamide, but fewer adverse effects. Belimumab in combination with standard therapy significantly decreases disease activity in SLE patients and is safe and well tolerated. Its role in patients with renal and neurological disease is still under investigation.

Rituximab has been reported as being effective in case reports and case series, but randomised placebo-controlled trials have not shown benefit.

**Maintenance therapy**

Following control of acute disease, oral prednisolone can be commenced in a dose of 40–60 mg daily, gradually reducing to 10–15 mg/day or less by 3 months. Azathioprine (2–2.5 mg/kg/day), MTX (10–25 mg/week) or MMF (2–3 g/day) may also be prescribed as steroid-sparing agents. The long-term aim is to try to maintain remission with the lowest dose of glucocorticoid and immunosuppressant possible. Cardiovascular risk factors, such as obesity, hypertension and hyperlipidaemia, should be controlled and patients should be advised to stop smoking and reduce excess alcohol intake.

Patients with SLE and the antiphospholipid antibody syndrome, who have had previous thrombosis, require life-long warfarin therapy. Patients with SLE are at risk of osteoporosis and hypovitaminosis D, and accordingly should be screened with biochemistry and DXA scanning.

**Systemic sclerosis**

Systemic sclerosis (SSc) is an autoimmune disorder of connective tissue, which results in fibrosis affecting the skin, internal organs and vasculature. It is characterised by severe Raynaud’s phenomenon, digital ischaemia (Fig. 26.48), sclerodactyly, cardiac, lung, gut and renal disease. The peak age of onset is in the fourth and fifth decades. It is a rare condition with a prevalence of 10–20 per 100,000, with a 4:1 female-to-male ratio. It is subdivided into limited cutaneous systemic sclerosis (lcSSc: 70% of cases) and diffuse cutaneous systemic sclerosis (dcSSc: 30% of cases) depending on the extent of skin involvement and presence of major organ involvement. Some patients with lcSSc have calcinosis and telangiectasia and when combined with Raynaud’s phenomenon, oesophageal involvement and sclerodactyly this is referred to as theCREST syndrome (Calcinosus, Raynaud’s, oEsophageal involvement, Sclerodactyly and Telangiectasia), which has a good prognosis. The prognosis in dcSSc is poor (5-year survival about 70%). Features that associate with a poor prognosis include older age, diffuse skin disease, proteinuria, high ESR, a low gas transfer factor for carbon monoxide (TLCO) and pulmonary hypertension.
Raynaud’s phenomenon
This is a universal feature and can precede other features by many years. Involvement of small blood vessels in the extremities may cause critical tissue ischaemia, leading to localised distal skin infarction and necrosis.

Musculoskeletal features
Arthralgia and flexor tenosynovitis are common. Restricted hand function is due to skin involvement rather than joint disease and erosive arthropathy is uncommon. Muscle weakness and wasting can result from myositis.

Gastrointestinal involvement
Smooth muscle atrophy and fibrosis in the lower two-thirds of the oesophagus lead to reflux with erosive oesophagitis. Dysphagia and odynophagia may also occur. Involvement of the stomach causes early satiety and occasionally outlet obstruction. Recurrent occult upper gastrointestinal bleeding may indicate a ‘watermelon’ stomach (antral vascular ectasia; up to 20% of patients). Small intestine involvement may lead to malabsorption due to bacterial overgrowth and intermittent bloating, pain or constipation. Dilatation of bowel due to autonomic neuropathy may cause pseudo-obstruction with nausea, vomiting, abdominal discomfort and distension, often worse after food (symptoms can mimic those of an acute abdomen and can lead to erroneous laparotomy).

Pulmonary involvement
Pulmonary hypertension complicates long-standing disease and is six times more prevalent in lcSSc than in dcSSc. It usually presents with insidiously evolving exertional dyspnoea and signs of right heart failure. Interstitial lung disease is common in patients with dcSSc who have topoisomerase 1 antibodies (ScI70). Dyspnoea can evolve slowly over time or rapidly in occasional cases.

Renal involvement
One of the main causes of death is hypertensive renal crisis, characterised by rapidly developing accelerated phase hypertension and renal failure. Hypertensive renal crisis is much more likely to occur in dcSSc than in lcSSc, and in patients with topoisomerase 1 and RNP antibodies.

Investigations
As SScl can affect multiple organs, routine haematology, renal, liver and bone function tests and urinalysis are essential. ANA is positive in about 95%. About 30% of patients with dcSSc have antibodies to topoisomerase 1 (ScI70). About 60% of patients have anticientromere antibodies and this is a biomarker for lcSSc and CREST syndrome. Chest X-ray, transthoracic echocardiography and lung function tests are recommended to assess for interstitial lung disease and pulmonary hypertension (low corrected transfer factor may indicate early pulmonary hypertension). High-resolution lung CT is recommended if interstitial lung disease is suspected. If pulmonary hypertension is suspected, right heart catheter measurements should be arranged at a specialist cardiac centre. A barium swallow can assess oesophageal involvement. A hydrogen breath test can indicate small intestinal bacterial overgrowth.

Management
For most patients, the focus of management is to ameliorate symptoms and combat the effects of the disease on target organs. In patients with severe dcSSc, encouraging results have been obtained with autologous stem cell transplantation following myeloablative therapy with cyclophosphamide.

- Raynaud’s phenomenon and digital ulcers. Avoidance of cold exposure, use of thermal insulating gloves/socks and maintenance of a high core temperature all help. If symptoms are persistent, calcium channel blockers, losartan, fluoxetine, sildenafil and tadalafil can be effective. Courses of intravenous prostaoycyclic are used for severe disease and critical ischemia. The endothelin-1 antagonist bosantan is
**Mixed connective tissue disease**

Mixed connective tissue disease (MCTD) is a condition in which some clinical features of SSc, myositis and SLE all occur in the same patient. It commonly presents with indolent puffiness of the fingers (the appearance is between that of SpA-type dactylitis and sclerodactyly) with Raynaud’s phenomenon and myalgias. Most patients have anti-RNP antibodies. Management focuses on treating the individual components of the disease (see other sections).

**Sjögren syndrome**

Sjögren syndrome (SS) is characterised by grittiness of the eyes and dryness of the mouth due to lymphocytic infiltration of salivary and lacrimal glands, leading to glandular fibrosis and exocrine failure. The typical age of onset is between 40 and 50 years, with a 9:1 female-to-male ratio. It is subdivided into primary Sjögren syndrome (PSS), which occurs in the absence of other autoimmune disease, and secondary Sjögren syndrome, where it occurs in association with other conditions like RA and SLE.

**Clinical features**

The eye symptoms, termed keratoconjunctivitis sicca, are due to a lack of lubricating tears, which reflects inflammatory infiltration of the lacrimal glands. Conjunctivitis and blepharitis are frequent and may lead to filamentary keratitis due to binding of tenacious mucous filaments to the cornea and conjunctiva. Oral involvement manifests as a dry mouth (xerostomia). There is a high incidence of dental caries, gingivitis, periodontitis and other dental problems. Lymphadenopathy is present in about two-thirds of patients and other sites of extraglandular involvement are listed in Box 26.64. Often the most disabling symptom is fatigue. There may be an association with inflammatory small-joint OA, although formal studies have not been done to determine if this is a chance association. Sialadenitis, osteoarthritis and xerostomia (SOX) syndrome has been described; this may occur independently of PSS or, more likely, constitutes a mild form. Both interstitial lung disease (presenting with dry cough, dyspnoea and course crackles on lung auscultation) and interstitial nephritis (presenting with polyuria and sometimes complicated by renal tubular acidosis) may occur and both require proactive screening. PSS is associated with a 40-fold increased lifetime risk of lymphoma, though the complication is still very rare. This should be suspected if there is progressive worsening of lymphadenopathy.

**Investigations**

Support for the diagnosis can be obtained by the Schirmer tear test, which measures tear flow over 5 minutes using absorbent paper strips placed on the lower eyelid; a normal result is more than 5 mm of wetting. Corneal staining with rose bengal may show punctate epithelial abnormalities over the area not covered by the open eyelid. If the diagnosis remains in doubt, it can be confirmed by demonstrating focal lymphocytic infiltrate in a minor salivary gland biopsy. Most patients have an elevated ESR and hypergammaglobulinaemia, and one or more autoantibodies, including ANA and RF are usually present. ANA-negative disease does exist, but in this case anti-Ro and anti-La antibodies are usually detectable (see Box 26.9). A chest X-ray, high resolution CT and lung function tests should be performed if symptoms suggestive of lung disease are present. Routine biochemistry and tests of urinary concentrating ability may be required if interstitial nephritis is suspected. Lymph node biopsy should be performed to exclude lymphoma in patients with progressive lymphadenopathy.

**Management**

No treatments can significantly modify the course of SS and so management is essentially symptomatic. Lacrimal substitutes, such as hypropromelose, should be used during the day in combination with more viscous lubricating application at night. Soft contact lenses can be useful for corneal protection in patients with filamentary keratitis and occlusion of the lacrimal ducts is occasionally needed. Artificial saliva sprays, salivary-stimulating tablets, pastilles and oral gels can be tried for xerostomia, but often chewing gum is most effective. Adequate post-prandial oral hygiene and prompt treatment of oral candidiasis are essential. Vaginal dryness is treated with lubricants. A trial of systemic plicarpine (5–30 mg daily in divided doses) is worthwhile in early disease to increase salivary and lacrimal secretions. HCQ (200 mg twice daily) is sometimes used in the treatment of SS, but clinical trials have not shown convincing evidence of benefit. Immunosuppression does not improve sicca symptoms, but is often used in the treatment of interstitial lung disease and interstitial nephritis although the evidence base for benefit is limited.

**Polymyositis and dermatomyositis**

Polymyositis (PM) and dermatomyositis (DM) are characterised by an inflammatory infiltrate of both skeletal and smooth muscle. In DM,
characteristic skin changes also occur. Both diseases are rare, with an incidence of 2–10 cases per million/year. They can occur in isolation or in association with other autoimmune diseases and both may be the presenting features of a previously undiagnosed malignancy.

**Clinical features**

The typical presentation of PM and DM is with symmetrical proximal muscle weakness over a few weeks, usually affecting the lower limbs more than the upper, in adults between 40 and 60 years of age. Patients report difficulty rising from a chair, climbing stairs and lifting. Muscle pain is not a prominent feature but may be present in up to one-third of patients. Systemic features of fever, weight loss and fatigue are common. Subcutaneous calcification associated with skin ulceration may occur in both DM and PM. Respiratory or pharyngeal muscle involvement can lead to ventilatory failure or aspiration that requires urgent treatment. Intestinal lung disease occurs in up to 30% of patients and is associated with the presence of antisynthetase (Jo-1) antibodies.

The skin lesions in DM include Gottron’s papules, which are scaly, erythematous or violaceous, psoriasiform plaques occurring over the extensor surfaces of PIP and DIP joints, and a heliotrope rash that is a violaceous discoloration of the eyelid in combination with periorbital oedema (Fig. 26.50). Similar rashes occur on the upper back, chest and shoulders over a ‘shawl’ distribution. Periungual nail-fold capillaries are often enlarged and tortuous.

**Investigations**

Muscle biopsy is the pivotal investigation and shows the typical features of fibre necrosis, regeneration and inflammatory cell infiltrate (Fig. 26.51). Since muscle involvement may be patchy, it is common to perform an MRI scan prior to biopsy, which often shows features of increased signal intensity in STIR sequence images. This not only provides support for the diagnosis, but also can help choose the optimal site for a biopsy. Serum levels of creatine kinase are typically raised and are a useful measure of disease activity, although a normal creatine kinase does not exclude the diagnosis, particularly in juvenile myositis. Electromyography is very useful for highlighting non-autoimmune/non-inflammatory myopathies. Screening for underlying malignancy should be undertaken routinely (full examination, chest X-ray, serum urine and protein electrophoresis, CT of chest/abdomen/pelvis; prostate-specific antigen in men and mammography in women).

**Management**

Oral glucocorticoids (prednisolone 1 mg/kg daily) are the first-line treatment of PM and DM, but high-dose intravenous methylprednisolone (1 g/day for 3 days) may be required in patients with respiratory or pharyngeal weakness. If there is a good response, glucocorticoids should be reduced by approximately 25% per month aiming for a maintenance dose of 5–7.5 mg daily. Glucocorticoid-induced myopathy should be considered in patients who initially respond but then relapse. A second muscle biopsy can be of diagnostic value to guide further treatment in this situation since in the case of glucocorticoid myopathy type II fibre atrophy is observed as compared with fibre necrosis and regeneration in active myositis. Treatment should be adjusted accordingly. Although most patients respond well to glucocorticoids, additional immunosuppressive therapy may be required as steroid-sparing agents in the form of MTX, azathioprine, MMF or cyclosporin. Rituximab is sometimes used in refractory cases, but the only randomised trial of this agent did not show benefit over placebo. Intravenous immunoglobulin (IVIg) has been shown to be effective in the treatment of DM and is often used in the treatment of refractory PM and DM. Antimalaria such as HCQ and mepacrine have been used for skin-predominant disease, but the evidence for benefit is limited and based on case reports.

**Juvenile dermatomyositis**

Juvenile dermatomyositis (JDM) is by far the most common inflammatory myopathy in children and adolescents, and typically does not require a search for malignancy. The incidence is 2–4 per million (United States and UK), with a median age of onset of 7 years (25% are below 4 years at diagnosis). Many clinical features are similar to those in the adult disease. JDM can be monocyclic, lasting up to 3 years (25%–40%), or polycyclic with periods of remission and relapse (60%–75%). In some cases, polycyclic JDM can be chronic and life-long. Skin ulceration occurs in 10%–20% of cases and calcinosis in about 30%.

Intravenous methylprednisolone, then oral glucocorticoids and MTX produce a rapid response in many cases. Cyclophosphamide may be used for resistant disease with skin ulceration. IVIg is given in resistant cases.

**Undifferentiated autoimmune connective tissue disease**

The term undifferentiated autoimmune connective tissue disease is used to describe the situation where patients present with individual clinical features of AICTD, either simultaneously or sequentially, but do not meet the criteria for diagnosis of a specific disease. Some of these individuals may progress to develop a specific AICTD with time; others continue to have an undifferentiated disease that remains the same for many years, and in others the symptoms will recede. These patients should be kept under review with management directed at treating individual symptoms as they arise.
**Adult-onset Still's disease**

Adult-onset Still's disease is a rare systemic inflammatory disorder of unknown cause with features that are in some respects similar to SJIA and familial fever syndromes (p. 71). The presentation is with intermittent fever, rash and polyarthritis or polyarthralgia. There is evidence that increased production of the pro-inflammatory cytokine interleukin-1 may play a pathogenic role. Spleenomegaly, hepatomegaly and lymphadenopathy may be present. Investigations typically provide evidence of an acute phase response with raised ESR and CRP and a markedly elevated serum ferritin. Tests for RF and ANA are negative. Treatment with NSAIDs can be effective in mild cases, but in more severe disease, glucocorticoids with or without DMARD such as azathioprine, MTX or MMF, are indicated. In resistant disease, the interleukin-1 inhibitors canakinumab or anakinra can be highly effective.

**Vasculitis**

Vasculitis is characterised by inflammation and necrosis of blood vessel walls, with associated damage to skin, kidney, lung, heart, brain and gastrointestinal tract. There is a wide spectrum of involvement and severity, ranging from mild and transient disease affecting only the skin, to life-threatening fulminant disease with multiple organ failure. Principal sites of involvement for the main types of vasculitis are summarised in Figure 26.52. The clinical features result from a combination of local tissue ischaemia (due to vessel inflammation and narrowing) and the systemic effects of widespread inflammation. Systemic vasculitis should be considered in any patient with fever, weight loss, fatigue, evidence of multisystem involvement, rashes, raised inflammatory markers and abnormal urinalysis (Box 26.65).

**Antineutrophil cytoplasmic antibody-associated vasculitis**

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) is a life-threatening disorder characterised by inflammatory infiltration of small blood vessels, fibrinoid necrosis and the presence of circulating antibodies to antineutrophil cytoplasmic antibody (ANCA). The combined incidence is about 10–15/1000000. There are three main subtypes with differing clinical features:

- **Microscopic polyangiitis**
  - Microscopic polyangiitis (MPA) is a necrotising small-vessel vasculitis found with rapidly progressive glomerulonephritis, often in association with alveolar haemorrhage. Cutaneous and gastrointestinal involvement is common and other features include neuropathy (15%) and pleural effusions (15%). Patients are usually myeloperoxidase (MPO) antibody-positive.

- **Granulomatosis with polyangiitis**
  - Granulomatosis with polyangiitis (GPA), also known as Wegener’s granulomatosis, is characterised by granuloma formation, mainly affecting the nasal passages, airways and kidneys. A minority of patients present with glomerulonephritis. The most common presentation of GPA is with epistaxis, nasal crusting and sinusitis, but haemoptysis and mucosal ulceration may also occur. Deafness may be a feature due to inner ear involvement and proptosis may occur because of inflammation of the retro-orbital tissue (Fig. 26.53). This causes diplopia due to entrapment of the extra-ocular muscles, or loss of vision due to optic nerve compression. Disturbance of colour vision is an early feature of optic nerve compression. Untreated nasal disease ultimately leads to destruction of bone and cartilage. Migratory pulmonary infiltrates and nodules occur in 50% of patients (as seen on high-resolution CT of lungs). Patients with GPA are usually proteinase-3 (PR3) antibody-positive.

**Eosinophilic granulomatosis with polyangiitis**

Eosinophilic granulomatosis with polyangiitis (EGPA), also known as Churg–Strauss syndrome, is a small-vessel vasculitis with an incidence of about 1–3 per 1 000 000. Antibodies to MPO or PR3 can be detected in up to 60% of cases. It is somewhat distinct from MPA and GPA in that eosinophilia is a prominent feature. Some patients have a prodromal period for many years, characterised by allergic rhinitis, nasal polyposis and late-onset asthma that is often difficult to control. The typical acute presentation is with a triad of skin lesions (purpura or nodules), asymmetric mononeuropathy multiplex and eosinophilia. Pulmonary infiltrates and pleural or pericardial effusions due to serositis may be present. Up to 50% of patients have abdominal symptoms provoked by mesenteric vasculitis.

**Investigation of AAV**

Patients with active disease usually have a leucocytosis with elevated CRP and ESR. Complement levels are usually normal or slightly elevated. Eosinophilia is common in EGPA. Imaging of the upper airways, chest and nasal passages with MRI can be useful in localising abnormalities in
GPA. Often, the diagnosis of AAV can be made on clinical and serological grounds in combination with the laboratory abnormalities described above, but if there is any doubt the diagnosis should be confirmed by biopsy of the kidney, skin or lesions in the sinuses and upper airways.

Management
Management of organ-threatening AAV is with high-dose glucocorticoids and immunosuppressive therapy. A commonly used regimen is pulse intravenous methylprednisolone 0.5–1g for 3 days coupled with intravenous cyclophosphamide 15mg/kg every 2 weeks for 3 months. This is followed by maintenance therapy with lower-dose glucocorticoids and azathioprine, MTX or MMF. Rituximab in combination with high-dose glucocorticoids has been shown to be equally effective as oral cyclophosphamide and glucocorticoids at inducing remission in AAV. Plasmapheresis should be considered for fulminant lung disease. High dose glucocorticoids and MTX are an effective combination for treating limited AAV where there is indolent sinus, lung or skin disease. Recently mepolizumab, an inhibitor of IL-5, has been shown to reduce the risk of relapse when combined with glucocorticoids in EGPA. Patients with AAV must be followed on a regular and long-term basis since the condition has a tendency to relapse, monitoring urinalysis for blood and protein, plasma creatinine, FBC, ESR, CRP, lung function and PR3 or MPO antibody titres.

Takayasu arteritis
Takayasu arteritis affects the aorta, its major branches and occasionally the pulmonary arteries. The typical age at onset is 25–30 years, with an 8:1 female-to-male ratio. It has a worldwide distribution, but is most common in Asia. It is characterised by granulomatous inflammation of the vessel wall, leading to its occlusion or weakening. It presents with claudication, fever, arthralgia and weight loss. Clinical examination may reveal loss of pulses, bruits, hypertension and aortic incompetence. Investigation typically shows a raised ESR and CRP and a normochromic, normocytic anaemia. The pivotal investigation is CT or MRI angiography, which reveals thickening of the vessel wall and narrowing of the lumen. Aortic coarctation, and aneurysmal dilatation may also occur. The diagnosis can also be made by 18F-fluorodeoxyglucose PET-CT imaging, where there is increased tracer uptake in affected vessels. Treatment is with high-dose glucocorticoids and immunosuppressants, as described for ANCA-associated vasculitis. With successful treatment, the 5-year survival is 83%.

Kawasaki disease
Kawasaki disease is a vasculitis that mostly involves the coronary vessels. It presents as an acute systemic disorder, usually affecting children under 5 years. It occurs mainly in Japan and other Asian countries, such as China and Korea, but other ethnic groups may also be affected. Presentation is with fever, generalised rash (including palms and soles), inflamed oral mucosa and conjunctival injection resembling a viral exanthem. The cause is unknown, but is thought to be an abnormal immune response to an infectious trigger. A syndrome with some similarities to Kawasaki disease has recently been reported to be a complication of COVID-19 infection in children. Cardiovascular complications include coronary arteritis, leading to myocardial infarction, transient coronary dilatation, myocardiitis, pericarditis, peripheral vascular insufficiency and gangrene. Treatment is with aspirin (5mg/kg daily for 14 days) and IV Ig (400mg/kg daily for 5 days). Ciclosporin (5mg/kg/day) in combination with IV Ig can be effective in patients with resistant disease.

Polyarteritis nodosa
Polyarteritis nodosa has a peak incidence between the ages of 40 and 50, with a male-to-female ratio of 2:1. The annual incidence is about 2/100000. Hepatitis B is an important risk factor and the incidence is 10 times higher in the Inuit of Alaska, in whom hepatitis B infection is endemic. Presentation is with fever, myalgia, arthralgia and weight loss, in combination with manifestations of multisystem disease. The most common skin lesions are palpable purpura (Fig. 26.54), ulceration, infection and livedo reticularis (see Fig. 26.47). Pathological changes comprise necrotising inflammation and vessel occlusion, and in 70% of patients, arteritis of the vasa nervorum leads to neuropathy, which is typically symmetrical and affects both sensory and motor function. Severe hypertension and/or renal impairment may occur due to multiple renal infarctions, but glomerulonephritis is rare (in contrast to MPAP). The diagnosis is confirmed by conventional or MR angiography, which shows multiple aneurysms and smooth narrowing of mesenteric, hepatic or renal systems, or by muscle or sural nerve biopsy, which reveals the histological changes described above. Treatment is with high-dose glucocorticoids and cyclophosphamide, as described for ANCA-associated vasculitis.

Giant cell arteritis and polymyalgia rheumatica
Giant cell arteritis (GCA) is a granulomatous arteritis that affects medium- and large-sized arteries. It is commonly associated with polymyalgia rheumatica (PMR), which presents with symmetrical pain and stiffness affecting the shoulder and pelvic girdle. There is evidence that these symptoms are due to an inflammatory infiltrate of the synovium and
tendon sheaths in the affected regions. Since many patients with GCA have symptoms of PMR, and some patients with PMR go on to develop GCA if untreated, many rheumatologists consider them to be different manifestations of the same underlying disorder. Both diseases are rare under the age of 60 years. The average age at onset is 70, with a female-to-male ratio of about 3:1. The prevalence of GCA in people of European descent is about 20 per 100,000 in those over the age of 50 years, while PMR affects about 60 per 100,000. Both conditions are much less common (1 in 100,000) in African and Asian populations. The cause is unknown, but there is a strong genetic component such that GCA is strongly associated with genetic variation at the HLA-DRB1 locus.

**Clinical features**

The cardinal symptom of GCA is headache, which is often localised to the temporal or occipital region and may be accompanied by scalp tenderness. Jaw pain develops in some patients, brought on by chewing or talking and is referred to as jaw claudication. Visual disturbance can occur (most specifically amaurosis) and a catastrophic presentation is with blindness in one eye due to occlusion of the posterior ciliary artery. In such cases the optic disc may appear pale and swollen with haemorrhages, but these changes may take 24–36 hours to develop and the fundus may initially appear normal. Rarely, neurological involvement may occur, with transient ischaemic attacks, brainstem infarcts and hemiparesis.

In GCA, constitutional symptoms, such as weight loss, fatigue, malaise and night sweats, are common. With PMR, there may be stiffness and painful restriction of active shoulder movements on waking. Sometimes patients can present with symptoms that are similar to RA. The affected muscles are not tender and there is no weakness or muscle-wasting. Other conditions that cause PMR-like symptoms are shown in Box 26.66.

**Investigations**

The typical laboratory abnormality is an elevated ESR and CRP, often with a normochromic, normocytic anaemia. Abnormal liver function tests may also occur. Very rarely, PMR and GCA can present with a normal ESR in the early stages of disease evolution. More objective evidence for GCA should be obtained whenever possible. The two most commonly used investigations are temporal artery biopsy and ultrasound of the temporal arteries. Characteristic biopsy findings are fragmentation of the internal elastic lamina with necrosis of the media in combination with a mixed inflammatory cell infiltrate. The sensitivity is about 70% with multiple biopsies and multiple section analysis (to detect ‘skip’ lesions), but a negative biopsy does not exclude the diagnosis. The characteristic finding on Doppler ultrasound examination is the ‘halo’ sign, where the thickened vessel wall shows as a dark area surrounding a positive Doppler signal within the vessel. The overall sensitivity is about 55% and specificity about 70% in routine clinical practice. A negative result does not exclude the diagnosis.

---

**Management**

Prednisolone should be commenced urgently in suspected GCA because of the risk of visual loss (Box 26.67). Response is dramatic, such that symptoms largely resolve within 48–72 hours of starting therapy in virtually all patients. It is customary to use higher doses in GCA (40–60 mg prednisolone) than in PMR (15–20 mg). In both conditions, the glucocorticoid dose should be progressively reduced, guided by symptoms and ESR, with the aim of reaching a dose of 10–15 mg by about 8 weeks. The rate of reduction should then be slowed by 1 mg per month. The IL-6 inhibitor tocilizumab has been shown to reduce the risk of relapse following glucocorticoid dose reductions in GCA and is of value in patients at high risk of glucocorticoid side effects. The long-term efficacy of tocilizumab in GCA remains under investigation. If symptoms recur, the dose should be increased to that previously controlled the symptoms and reduction attempted again in another few weeks. Immunosuppressive therapy with MTX or azathioprine may be required as steroid-sparing agents in patients where it is not possible to reduce the prednisolone dose below 10 mg daily. Most patients need glucocorticoids for an average of 12–24 months and in view of this bisphosphonate therapy is often required to protect against osteoporosis.

**Henoch–Schönlein purpura**

Henoch–Schönlein purpura is a small-vessel vasculitis caused by immune complex deposition following an infectious trigger. It is predominantly a disease of children and young adults. The usual presentation is with purpura over the buttocks and lower legs, accompanied by abdominal pain, gastrointestinal bleeding and arthralgia. Nephritis can also occur and may present up to 4 weeks after the onset of other symptoms. Biopsy of affected tissue shows a vasculitis with IgA deposits in the vessel wall. Henoch–Schönlein purpura is usually a self-limiting disorder that settles spontaneously without specific treatment. Glucocorticoids and immunosuppressive therapy may be required in patients with more severe disease, particularly in the presence of nephritis.

**Cryoglobulinemic vasculitis**

This is a small-vessel vasculitis that occurs when immunoglobulins precipitate out in the cold. Cryoglobulins are classified into three types (see Box 4.16). Types II and III are associated with vasculitis. The typical presentation is with a vasculitic rash over the lower limbs, arthralgia, Raynaud’s phenomenon and neuropathy. The ESR and CRP are elevated in active disease and C3 levels may be reduced. Some cases are secondary to hepatitis C infection and others are associated with other autoimmune diseases. Affected patients should be screened and, if positive, treated for hepatitis C. There is no consensus as to how best to treat cryoglobulinemic vasculitis in the absence of an obvious trigger. Glucocorticoids and immunosuppressive therapy are often used empirically, but their efficacy is uncertain. In severe cases, plasmapheresis can be considered.
sparing the lower non-cartilaginous portion. Around 30% of patients have coexisting autoimmune or connective tissue disease. Involvement of tracheobronchial cartilage may lead to a hoarseness, cough, stridor or expiratory wheeze. Other manifestations include collapse of the bridge of the nose, scleritis, hearing loss and cardiac valve dysfunction. Cartilage biopsy shows an inflammatory infiltrate in the perichondrium. Both ESR and CRP are raised in active disease. Pulmonary function tests, including flow–volume loops, should be performed to assess the degree of laryngotracheal disease, since this is an important cause of mortality. Mild disease usually responds to low-dose glucocorticoids or NSAIDs, whereas major tracheobronchial involvement requires high-dose glucocorticoids and immunosuppressants, as described for SLE.

### IgG4 disease

This is a rare condition (1–3/100,000) characterised by an inflammatory infiltrate of affected tissues in the early stages followed by fibrotic damage as the disease progresses. The disease may present in many ways, including with swelling of the lacrimal and salivary glands (mimicking Sjögren syndrome) and proptosis, sinusitis, hearing loss, interstitial lung disease and cranial nerve lesions (mimicking GPA). Inflammatory disease of the great vessels may occur while abdominal pain may result from infiltration of the pancreas or retroperitoneum. Thyroid involvement may manifest as Hashimoto’s thyroiditis and Reidel’s thyroiditis. The diagnosis may be suspected by the presence of an lymphocytic infiltrate on tissue biopsy, which is rich in IgG4-secreting plasma cells, and raised serum IgG4.

Management is with glucocorticoids (prednisolone 30–40 mg/day with progressive dose reduction guided by symptoms, inflammatory markers and IgG4 levels) and an immunosuppressive such as MTX, azathioprine or MMF. Intravenous rituximab has also been used successfully using a similar regimen as in RA.

### Diseases of bone

#### Osteoporosis

Osteoporosis is the most common bone disease. It has been estimated that more than 8.9 million fractures occur annually worldwide and most of these occur in patients with osteopenia or osteoporosis. About one-third of all women and one-fifth of men aged 50 and above suffer fractures at some point in life. The burden of osteoporosis-related fractures is predicted to increase by two- to threefold by 2050 on a worldwide basis, due to ageing of the population. Osteoporosis is under-diagnosed and under-treated throughout Asia, particularly in rural areas, due to low provision of technologies like DXA, which are required to make the diagnosis. Osteoporosis-related fractures can affect any bone, but common sites are the forearm (Colles’ fracture), spine (vertebral fractures), humerus and hip. All of these fractures become more common with increasing age (Fig. 26.56). Since only about one-third of vertebral fractures come to medical attention (clinical vertebral fractures), the true number of patients with vertebral fracture is likely to be much greater than that shown in Figure 26.56. Hip fractures are the most serious complication of osteoporosis and have an immediate mortality of about 12% and a continued increase in mortality of about 20% when compared with age-matched controls. Treatment of hip fracture accounts for the majority of the health-care costs associated with osteoporosis.

#### Pathophysiology

The defining feature of osteoporosis is reduced bone density, which causes micro-architectural deterioration of bone tissue and leads to an increased risk of fracture, in response to minor trauma. The risk of fracture increases markedly with age in both genders (see Fig. 26.56). This is mostly attributable to an increased risk of falling with age, but is also due in part to an age-related decline in bone density, especially in

---

**Behçet’s disease**

This is a vasculitis of unknown aetiology that characteristically targets small arteries and venules. It is rare in Western Europe but more common in ‘Silk Route’ countries, around the Mediterranean and in Japan, where there is a strong genetic association with HLA-B51.

Oral ulcers are invariably present (Fig. 26.55). Unlike aphthous ulcers, they are usually deep and multiple, and last for 10–30 days. Genital ulcers are also a common problem, occurring in 60%–80% of cases. The usual skin lesions are erythema nodosum or acniform lesions, but migratory thrombophlebitis and vasculitis also occur. Ocular involvement is common and may include anterior or posterior uveitis or retinal vasculitis. Neurological involvement occurs in 5% and mainly involves the brainstem, although the meninges, hemispheres and cord can also be affected, causing pyramidal signs, cranial nerve lesions, brainstem symptoms or hemiparesis. Recurrent thromboses also occur. Renal involvement is extremely rare.

The diagnosis is primarily made on clinical grounds (Box 26.68), but one characteristic feature that can be of diagnostic value is the pathergy test, which involves pricking the skin with a needle and looking for evidence of pustule development within 48 hours.

Oral and genital ulceration can be managed with a combination of colchicine and topical glucocorticoid preparations. Colchicine can be effective for erythema nodosum and arthralgia. Glucocorticoids and immunosuppressants such as azathioprine are indicated for ulcers, recurrent venous thrombosis and neurological disease. Anti-TNF-α therapy and/or thalidomide may be required in refractory patients.

---

**Relapsing polychondritis**

Relapsing polychondritis is a rare inflammatory disease of cartilage that classically presents with acute pain and swelling of one or both ear pinnae,
women (Fig. 26.57). Bone mass increases during growth to reach a peak between the ages of 20 and about 45 years, but falls thereafter in both genders with an accelerated phase of bone loss after the menopause in women due to oestrogen deficiency. The loss of bone with ageing is caused by an imbalance in the bone remodelling cycle, whereby the amount of new bone formed by osteoblasts cannot keep pace with the amount that is removed by osteoclasts (see Fig. 26.2). The reduction in bone formation is thought to be partly due to differentiation of bone marrow stem cells to adipocytes, as opposed to osteoblasts. Osteoporosis sometimes occurs because of failure to attain adequate levels of peak bone mass, but is more commonly due to age-related bone loss.

Osteoporosis is a complex disease that can occur in association with a wide variety of risk factors, as summarised in Box 26.69. Genetic factors account for up to 80% of variation in bone density and genome-wide association studies have shown that susceptibility is determined in part by a large number of common variants, some of which are involved in the RANK and Wnt signalling pathways (see Fig. 26.3). Rarely, osteoporosis may be caused by mutations in single genes. Environmental factors, such as exercise and calcium intake during growth and adolescence,
are important in maximising peak bone mass and in regulating rates of post-menopausal bone loss. Smoking has a detrimental effect on BMD and is associated with an increased fracture risk, partly because female smokers have an earlier menopause than non-smokers. Heavy alcohol intake is a recognised cause of osteoporosis and fractures, but moderate intake does not substantially alter risk.

**Idiopathic osteoporosis**

The term idiopathic osteoporosis is frequently used to describe the occurrence of osteoporosis in patients with no specific underlying cause. It is slightly misleading, since most, if not all, patients in this category have age-related osteoporosis or osteoporosis associated with inheritance of genetic variants that regulate bone density.

**Secondary osteoporosis**

Osteoporosis can occur in association with a variety of diseases and drug treatments, and in many cases more than one disease or risk factor is operative. The most important causes are summarised in *Box 26.69*. Secondary causes of osteoporosis are particularly common in men, occurring in up to 50% of patients. Hypogonadism, glucocorticoid use (see below) and alcohol excess are the most important predisposing factors.

**Glucocorticoid-induced osteoporosis**

Glucocorticoid-induced osteoporosis is a common problem in patients with systemic inflammatory and chronic pulmonary diseases. The risk of osteoporosis is related to dose and duration of glucocorticoid therapy and increases substantially in patients who have taken more than 7.5 mg of prednisolone daily for more than 3 months (or an equivalent dose of another glucocorticoid). Inhaled glucocorticoids can reduce bone density, but the risk of osteoporosis is much lower than with systemic therapy. Glucocorticoids mainly cause osteoporosis by inhibiting bone formation and causing apoptosis of osteoblasts and osteocytes. Other contributory mechanisms include inhibition of intestinal calcium absorption, increased renal excretion of calcium and secondary hyperparathyroidism, which stimulates osteoclastic bone resorption.

**Pregnancy-associated osteoporosis**

This is a rare form of osteoporosis that typically presents with back pain and multiple vertebral fractures usually during the third trimester or puerperium. It is discussed in more detail in Chapter 32.

**Clinical features**

Osteoporosis does not cause symptoms until a fracture occurs. Non-vertebral fractures are almost always caused by a traumatic event, most usually a simple fall. The term ‘fragility fracture’ is used to describe a fracture that occurs as the result of a fall from standing height or less. These are typical of osteoporosis. It is important to remember that the majority of people who suffer a fragility fracture do not have osteoporosis; some have normal BMD, but most have osteoporosis (Fig. 26.58). The clinical signs of fracture are pain, local tenderness and deformity. In hip fracture, the patient is (with rare exceptions) unable to weight-bear and has a shortened and externally rotated limb on the affected side. The presentation of vertebral fractures is variable. Some patients present with acute severe back pain. This may radiate to the anterior chest or abdominal wall and be mistaken for a myocardial infarction, aortic dissection or intra-abdominal pathology. In others the presentation is with height loss and kyphosis in the absence of pain or with chronic back pain. Osteoporosis may be suspected by the finding of radiological osteopenia or vertebral deformities on imaging that has been performed for other reasons.

**Investigations**

The most important investigation is DXA (see Fig. 26.9). This should be considered in patients aged over 50 who have already suffered a fragility fracture, and in those with clinical risk factors (Box 26.70) when a fracture risk assessment tool has returned an elevated value. The risk at which DXA should be performed remains a subject of debate, but a 10-year risk of over 10% has been suggested, since there is evidence of benefit from treatment at this level. Other indications for DXA are in patients under 50 years who have very strong risk factors, such as premature menopause or high-dose glucocorticoids. Figure 26.59 provides a suggested algorithm for the investigation of patients with suspected osteoporosis.
Fig. 26.59  Algorithm for the diagnosis and management of osteoporosis. ¹DXA scan advisable to obtain baseline BMD but not necessary to initiate treatment. ²One severe or two or more moderate vertebral fractures on X-ray, and T-score < −1.5 at any site or spine T score < −4.0. Adapted from SIGN 142. www.sign.ac.uk
A history should be taken to identify any predisposing causes, such as early menopause, excessive alcohol intake, smoking and glucocorticoid therapy. Signs of endocrine disease, neoplasia and inflammatory disease should be sought on clinical examination. A falls history should be taken and screening tests performed to assess the risk of falls (p. 1297). Screening for secondary causes of osteoporosis should be performed, as summarised in Box 26.71.

Management

The aim of treatment is to reduce the risk of fracture and this can be achieved by a combination of approaches.

Non-pharmacological interventions

Advice on smoking cessation, moderation of alcohol intake, adequate dietary calcium intake and exercise should be given. Those with recurrent falls or unsteadiness on a ‘get up and go’ test (p. 1297) should be referred to a multidisciplinary falls-prevention team. Hip protectors can reduce the risk of hip fracture in selected patients, but adherence is often poor.

Pharmacological interventions

Several drug treatments are now available to reduce the risk of fracture in osteoporosis. The dosages, mode of administration and indications are summarised in Box 26.72. More detail on the individual drugs is provided below.

Bisphosphonates Bisphosphonates are the first-line treatment for osteoporosis. These are a class of drugs with a central core of P-C-P atoms, to which various side-chains are attached. Following administration, they target bone surfaces and are ingested by osteoclasts during the process of bone resorption. The bisphosphonate is released within the osteoclast, causing cell death and thereby bone resorption. This in turn causes an increase in bone density, but this is principally due to increased mineralisation of bone, rather than an increase in bone mass (Fig. 26.60). Bisphosphonates reduce the risk of fractures in osteoporosis, but do not completely prevent the occurrence of fractures.

Oral bisphosphonates are typically given for a period of 5 years, at which point the need for continued therapy should be evaluated, with a repeat DXA if possible. If patients have remained free of fractures after 5 years and if BMD levels have increased and no longer remain in the osteoporotic range, it is usual to instigate a 5-year spell off therapy. Treatment may be continued for up to 10 years in patients whose BMD levels remain in the osteoporotic range after 5 years and in those with pre-existing vertebral fractures. A change in treatment should be considered in patients who have lost BMD despite oral bisphosphonates (more than 4% at any site). Most commonly, this will be a switch to parenteral zoledronic acid which is often given by annual infusion of 5 mg for 3 consecutive years followed by a spell of 2 years without treatment. Infusions every 18 months over a spell of 6 years have also been found to be effective for fracture prevention.

Oral bisphosphonates are poorly absorbed from the gastrointestinal tract and should be taken on an empty stomach with plain water; no
**26.73 Adverse effects of bisphosphonates**

**Common**
- Upper gastrointestinal intolerance (oral)
- Acute phase response (intravenous)

**Less common**
- Atrial fibrillation (intravenous zoledronic acid)
- Hypocalcaemia (intravenous bisphosphonates)
- Atypical subtrochanteric fractures

**Rare**
- Uveitis
- Osteonecrosis of the jaw
- Oesophageal ulceration

Food should be eaten for 30–45 minutes after administration. They are contraindicated in patients with oesophageal stricture or achalasia, since tablets may stick in the oesophagus, causing ulceration and perforation. Upper gastrointestinal upset occurs in about 5% of cases. Oral bisphosphonates can be used in patients with gastro-oesophageal reflux disease, but may cause worsening of symptoms. The most common adverse effect with intravenous bisphosphonates is a transient influenza-like illness with fever, malaise, anorexia and generalised aches, which occurs 24–48 hours after administration. This is self-limiting, but can be treated with paracetamol or NSAIDs if necessary. It predominantly occurs after the first exposure and tolerance develops thereafter. Other adverse effects are shown in Box 26.73. Osteonecrosis of the jaw is characterised by the presence of necrotic bone in the mandible or maxilla, typically occurring after tooth extraction when the socket fails to heal. This complication is very rare in osteoporosis, but patients receiving bisphosphonates should be advised to pay attention to good oral hygiene. There is no evidence that temporarily stopping bisphosphonates for tooth extraction alters the risk of osteonecrosis of the jaw. Atypical subtrochanteric fractures have been described in patients who have received long-term bisphosphonates and appear to be the result of over-suppression of normal bone remodelling. In the vast majority, the benefits of bisphosphonate therapy far outweigh the risks, but it is important for treatment to be targeted to patients with low BMD who are most likely to benefit.

**Denosumab** Denosumab is a monoclonal antibody that inhibits bone resorption by neutralising the effects of RANKL (see Fig. 26.2). It is administered by subcutaneous injection of 60 mg every 6 months in the treatment of osteoporosis and has similar efficacy to zoledronic acid. One potential adverse effect is hypocalcaemia, but this can be mitigated by calcium and vitamin D supplements. Denosumab may rarely cause osteonecrosis of the jaw and atypical subtrochanteric fractures. When denosumab is stopped, there is a rebound increase in bone turnover that can be associated with an increased risk of vertebral fracture and even hypercalcaemia. Because of this denosumab needs to be continued on a long-term basis; if it has to be stopped for any reason, bisphosphonate therapy should be given to inhibit the rebound increase in bone turnover.

**Calcium and vitamin D** Combined calcium and vitamin D supplements have limited efficacy in the prevention of osteoporotic fractures when given alone, but are widely used as an adjunct to other treatments. A typical daily dosage is 1000 mg calcium and 800 IU vitamin D. Calcium and vitamin D supplements have efficacy in preventing fragility fractures in old age or in institutionalised patients, who are at high risk of deficiency (Box 26.74). Vitamin D supplements alone do not prevent fractures in osteoporosis, but there is evidence that the response to bisphosphonates is blunted in patients with vitamin D deficiency. If the patient’s dietary calcium is sufficient, stand-alone vitamin D supplements (800 IU daily) can be prescribed as an adjunct to anti-osteoporosis therapies. Calcitriol (1,25(OH)₂D₃), the active metabolite of vitamin D, is licensed for treatment of osteoporosis but it is seldom used because the data on fracture prevention are less robust than for other agents.

**Teriparatide** Teriparatide (TPTD) is the 1–34 fragment of human PTH. It is an effective treatment for osteoporosis, which works by stimulating new bone formation. Although TPTD also stimulates bone resorption, the increase in bone formation is greater, resulting in increased bone density, particularly at sites rich in trabecular bone such as the spine. It is given by a self-administered subcutaneous injection in a dose of 20 μg daily for 2 years. At the end of this period, bisphosphonate therapy or another inhibitor of bone resorption should be administered to maintain the increase in BMD. Oral bisphosphonates and TPTD should not be given in combination, however, since the bisphosphonate blunts the anabolic effect. The efficacy of TPTD for prevention of non-vertebral fractures is similar to that of bisphosphonates, but it is superior to oral bisphosphonates in preventing vertebral fractures. The most common adverse effects are headache, muscle cramps and dizziness. Mild hypercalcaemia may occur, but it is usually asymptomatic and does not require discontinuation of treatment. Monitoring of serum calcium is not required during TPTD treatment.

**Abaloparatide** Abaloparatide is the 1–34 fragment of PTH-related protein which has effects similar to those of TPTD. It is given as a self-administered injection of 80 μg daily for 18 months. At the end of this period an inhibitor of bone resorption should be given to maintain the increase in bone mass. Efficacy has been demonstrated for the prevention of vertebral fractures.
Romosozumab This is a neutralising antibody to sclerostin, which is produced by osteocytes and acts to inhibit bone formation (see Fig. 26.3). Romosozumab is a highly effective treatment for osteoporosis and works by inhibiting bone resorption and stimulating bone formation. It is indicated for the treatment of severe osteoporosis, where it is given by self-administered subcutaneous injection 210mg once a month for 12 months. Following completion of treatment, an inhibitor of bone resorption should be given to maintain the increase in bone density. Romosozumab is significantly more effective than oral alendronic acid at preventing fractures of all types and it is one of the most effective treatments for osteoporosis currently available. Adverse effects are uncommon, although a slight excess of cardiovascular events was observed in some clinical trials and because of that it is contraindicated in patients with a previous history of myocardial infarction or stroke.

Hormone replacement therapy Cyclical HRT with oestrogen and progesterone prevents post-menopausal bone loss and reduces the risk of vertebral and non-vertebral fractures in post-menopausal women. It is primarily indicated for the prevention of osteoporosis in women with an early menopause and for treatment of women with osteoporosis in their early fifties who have troublesome menopausal symptoms. It is not recommended above the age of 60 because of an increased risk of breast cancer, cardiovascular disease and venous thromboembolism.

Tibolone Tibolone has partial agonist activity at oestrogen, progesterone and androgen receptors. It has been shown to prevent vertebral and non-vertebral fractures in post-menopausal osteoporosis. Treatment is associated with a slightly increased risk of stroke, but a reduced risk of breast cancer.

Surgery Orthopaedic surgery with internal fixation is frequently required to reduce and stabilise osteoporotic fractures. Patients with intracapsular fracture of the femoral neck generally need hemi-arthroplasty or total hip replacement in view of the high risk of osteonecrosis. Vertebroplasty is sometimes used in the treatment of painful vertebral compression fractures. It involves injecting methyl methacrylate (MMA) into the affected vertebral body under sedation and local anaesthesia. Randomised trials have not shown convincing evidence of benefit as compared with a sham procedure. Kyphoplasty is used under similar circumstances, but in this case a needle is introduced into the affected vertebral body and a balloon is inflated, which is then filled with MMA. It has similar efficacy to vertebroplasty. Serious adverse effects may occur with both procedures, including spinal cord compression due to leakage of MMA and fat embolism.

**Osteomalacia, rickets and vitamin D deficiency**

Osteomalacia and rickets are characterised by defective mineralisation of bone. The most common cause is vitamin D deficiency, but both conditions can also occur as the result of inherited defects in renal phosphate excretion, inherited defects in the vitamin D receptor and in the pathways responsible for vitamin D activation. Other causes are summarised in Box 26.75 and are discussed in more detail below. The term osteomalacia refers to the syndrome when it occurs in adults; rickets is the equivalent in children.
Vitamin D deficiency

Vitamin D deficiency is a biochemical diagnosis, which is defined to be present when serum 25(OH)D concentrations are below 25 nmol/L (10 ng/mL). People with vitamin D levels in the range 25–50 nmol/L (10–20 ng/mL) are said to have vitamin D insufficiency, whereas those with 25(OH)D levels above 50 nmol/L (20 ng/mL) are classified as having normal vitamin D status. The likelihood of developing vitamin D deficiency is strongly related to sunlight exposure. It is common in northern latitudes (or southern latitudes in the southern hemisphere) and shows seasonal variation. Vitamin D deficiency is more common in the winter and spring and less common in summer and autumn (for a UK example, see Fig. 26.61). People with dark skin and those who wear facial coverings are more prone to developing vitamin D deficiency.

Pathogenesis

The source of vitamin D and pathways involved in regulating its metabolism are shown in Figure 26.62. In normal individuals, vitamin D (also known as cholecalciferol) comes from two sources: about 70% is made in the skin, where 7-dehydrocholesterol is converted to cholecalciferol under the influence of ultraviolet light, whereas the remaining 30% is derived from the diet. The main dietary sources are oily fish and meat, although bread and dairy products are fortified with vitamin D in some countries. On entering the circulation, vitamin D is hydroxylated in the liver to form 25(OH) vitamin D and this is further hydroxylated in the kidney to form 1,25(OH)D, the biologically active metabolite. The 1,25(OH)D primarily acts on the gut to increase intestinal calcium absorption, but also acts on the skeleton to stimulate bone remodelling. Synthesis of 1,25(OH)D is regulated by a negative feedback loop orchestrated by the parathyroid glands. When vitamin D levels fall — as the result of lower sunlight exposure or dietary lack — production of 1,25(OH)D is reduced, causing a reduction in calcium absorption from the gut. This causes a transient fall in serum calcium, which is detected by calcium-sensing receptors on the parathyroid chief cells; this increases PTH secretion, which restores calcium levels to normal. Vitamin D deficiency is, therefore, usually characterised by a low level of 25(OH)D and a raised level of PTH. Sometimes, low 25(OH)D levels may be observed in the presence of a normal PTH concentration. This is of uncertain clinical significance and can be due to variations in levels of vitamin D-binding protein. Serum concentrations of vitamin D are under genetic control and are associated with variants close to the GC gene, which encodes vitamin D-binding protein.

**Fig. 26.61** Seasonal changes in vitamin D concentrations. (To convert nmol/L to ng/mL, multiply by 2.5.) Adapted from McDonald HM, Mavroeidi A, Fraser WD, et al. Sunlight and dietary contributions to the seasonal vitamin D status of cohorts of healthy postmenopausal women living at northerly latitudes: a major cause for concern? Osteoporos Int 2011; 22:2461–2472.

**Fig. 26.62** Vitamin D metabolism. Vitamin D is produced in the skin from 7-dehydrocholesterol (7-DHC) by ultraviolet B (UVB) light. The 7-dehydrocholesterol reductase enzyme, which is encoded by the DCHR7 gene, opposes the effect of UVB by converting 7-DHC to cholesterol. The vitamin D then undergoes hydroxylation steps in the liver and kidney to form the active metabolite 1,25(OH)₂D, which regulates calcium homeostasis by stimulating calcium absorption from the diet and bone resorption. See text for details. (PTH = parathyroid hormone)
protein; the DHCR7 gene, which encodes 7-dehydrocholesterol reductase, responsible for catalysing conversion of 7-DHC to cholesterol; the CYP2R1 gene, which encodes vitamin D-25-hydroxylase, responsible for hydroxylation of vitamin D in the liver; and the CYP24A1 gene, which encodes vitamin D-24-hydroxylase, responsible for converting 25(OH)D to the inactive metabolite 24,25(OH)2D.

Clinical features

Low circulating levels of vitamin D do not cause symptoms unless the vitamin D deficiency is severe, so the diagnosis of vitamin D deficiency is primarily made as the result of biochemical testing. A wide range of diseases, including most types of cancer, diabetes, multiple sclerosis and chronic inflammatory diseases have been associated with vitamin D deficiency. Current evidence suggests that these are not causal associations, but explained by confounding whereby people who are unwell have reduced sunlight exposure and poor diet. If vitamin D deficiency is prolonged and severe, then osteomalacia and rickets may occur, as discussed below.

Investigations

The diagnosis can be made by measurement of serum 25(OH)D. In patients with low 25(OH)D, measurements of PTH, serum calcium, phosphate and ALP should also be considered. Low levels of 25(OH)D in the absence of other abnormalities is unlikely to be of any clinical significance and in many cases is likely to be due to low levels of vitamin D-binding protein, the levels of which are genetically determined. If low 25(OH)D levels are combined with raised levels of PTH, this is of more significance since it indicates secondary hyperparathyroidism, which if untreated and prolonged, may impair bone health and eventually lead to osteomalacia or rickets.

Management

Vitamin D supplements should be considered in patients who have low 25(OH)D levels and raised levels of PTH. In most young adults, greater exposure to UV light and cholecalciferol in a dose of 800 IU daily should be sufficient to correct the deficiency. Short courses of high-strength vitamin D can also be used, such as 200000 I.U. once weekly for 4–6 weeks. The benefit of treating low 25(OH)D values in the absence of other abnormalities of calcium biochemistry is uncertain. There is some evidence that response to bisphosphonate treatment of osteoporosis is impaired in patients with vitamin D deficiency and this is an indication for supplements. Similarly, patients who are receiving intravenous bisphosphonates and denosumab for osteoporosis should have vitamin D deficiency corrected by supplementation to reduce the risk of hypocalcaemia.

Osteomalacia and rickets

Severe and prolonged vitamin D deficiency can result in the occurrence of osteomalacia in adults and rickets in children. Improvements in nutrition mean that these are now relatively uncommon conditions in high-income countries, but they remain prevalent in older housebound individuals, who may have a poor diet and limited sunlight exposure, in women who wear facial coverings such as the niqab or burka, and in people with malabsorption.

Pathogenesis

Osteomalacia and rickets occur as the result of chronic secondary hyperparathyroidism, which invariably accompanies severe and long-standing vitamin D deficiency. The sustained elevation in PTH levels maintains normal levels of serum calcium by increasing bone resorption, which eventually causes progressive demineralisation of the skeleton. Phosphate released during the process of bone resorption is lost through increased renal excretion, resulting in hypophosphataemia. The raised levels of PTH stimulate osteoblast activity and cause new bone formation, but the matrix is not mineralised properly because of deficiency of calcium and phosphate. The under-mineralised bone is soft, mechanically weak and subject to fractures, particularly stress fractures. Normal levels of serum calcium tend to be maintained until a very advanced stage, when hypocalcaemia may occur.

Clinical features

Vitamin D deficiency in children causes delayed development, muscle hypotonia, cranioftabes (small unossified areas in membranous bones of the skull that yield to finger pressure with a cracking feeling), bossing of the frontal and parietal bones and delayed anterior fontanelle closure, enlargement of epiphyses at the lower end of the radius and swelling of the ribs costochondral junctions (‘rickety rosary’). Osteomalacia in adults can present with fractures and low BMD, mimicking osteoporosis. Other symptoms include bone pain and general malaise. Proximal muscle weakness is prominent and the patient may walk with a waddling gait and struggle to climb stairs or stand up from a chair. There may be bone and muscle tenderness on pressure and focal bone pain can be due to fissure fractures of the ribs and pelvis.

Investigations

The diagnosis can usually be made by measurement of serum 25(OH)D, PTH, calcium, phosphate and ALP. Typically, serum ALP levels are raised, 25(OH)D levels are undetectable and PTH is markedly elevated. Serum phosphate levels tend to be low, but serum calcium is usually normal, unless the disease is advanced. X-rays often show osteopenia or vertebral crush fractures and, with more advanced disease, focal radiolucent areas (pseudofractures or Looser zones) may be seen in ribs, pelvis and long bones (Fig. 26.63). In children, there is thickening and widening of the epiphysial plate. A radionuclide bone scan may show multiple hot spots in the ribs and pelvis at the site of fractures and the appearance may be mistaken for metastases. Where there is doubt, the diagnosis can be confirmed by bone biopsy, which shows the pathognomonic increased thickness and extent of osteoid seams (see Fig. 26.63).

Management

Osteomalacia and rickets respond promptly to treatment with vitamin D. A wide variety of doses can be used. Treatment with between 10 000 and 25 000 IU daily for 2–4 weeks is associated with rapid clinical improvement, an elevation in serum 25(OH)D and a reduction in PTH. Serum ALP levels sometimes rise initially as mineralisation of bone increases, but eventually fall to within the reference range as the bone disease heals. Subsequently, the dose of vitamin D can usually be reduced to a maintenance level of 800–1600 IU daily (10–20 µg), except in patients with malabsorption, who may require higher maintenance doses.

Vitamin D-resistant rickets

This is a genetically determined condition that presents in childhood with rickets that is resistant to therapy with vitamin D in standard dosages.

Fig. 26.63 Osteomalacia. A Photomicrograph of a toluidine blue-stained bone biopsy from a patient with osteomalacia showing thickened osteoid seams, stained light blue (arrows) covering most of the bone surface (left). Calcified bone is stained purple. B X-ray of a patient with osteomalacia showing a stress fracture of the tibia (arrow).
**Pathogenesis**

Type I vitamin D-resistant rickets (VDRR) is caused by inactivating mutations in the 25(OH)D-1α-hydroxylase (CYP27B1) enzyme, which converts 25(OH)D to the active metabolite 1,25(OH)₂D₃. Type II VDDR is caused by inactivating mutations in the vitamin D receptor, which impair its ability to activate gene transcription. Both are recessive disorders and consanguinity is common.

**Clinical features**

These are as described above for infantile rickets. The diagnosis is usually first suspected when the patient fails to respond to vitamin D supplementation.

**Investigations**

The biochemical features of type I VDDR are similar to those of ordinary vitamin D deficiency, except that levels of 25(OH)D are normal, but 1,25(OH)₂D₃ is low. In type II VDDR, 25(OH)D is normal, but PTH and 1,25(OH)₂D₃ values are raised. The diagnosis can be confirmed by genetic testing.

**Management**

Type I VDDR responds fully to treatment with the active vitamin D metabolites 1α-hydroxy-vitamin D (1–2 μg daily, orally) or 1,25-dihydroxy-vitamin D (0.25–1.5 μg daily, orally). Calcium supplements are not necessary unless there is dietary deficiency. Type II VDDR sometimes responds partially to very high doses of active vitamin D metabolites, which can activate the mutant receptor, although additional calcium and phosphate supplements are also necessary.

**Hereditary hypophosphataemic rickets**

This group of disorders are caused by inherited defects in renal tubular phosphate reabsorption. The most common is X-linked hypophosphataemic rickets (XLRH), but autosomal dominant and autosomal recessive forms also occur (see Box 26.75).

**Pathophysiology**

Most forms of hereditary hypophosphataemia are associated with raised circulating concentrations of the phosphate-regulating hormone fibroblast growth factor 23 (FGF23). This hormone is produced by osteocytes (see Fig. 26.3) and enters the circulation, where it is normally inactivated by proteolytic cleavage. Production of FGF23 by osteocytes is under tonic inhibition by DMP1 and PHEX. In XLRH, the inhibitory effect on FGF23 production is lost due to mutations in PHEX and a similar situation occurs in autosomal recessive hypophosphataemic rickets (ARHR1) due to loss-of-function mutations in DMP1. In autosomal dominant hypophosphataemic rickets (ADHR), the FGF23 protein carries mutations that prevent FGF23 being degraded, thereby causing accumulation of intact FGF23 hormone in the circulation. In all three diseases, the elevation in FGF23 results in osteomalacia and rickets by causing phosphaturia by up-regulation of sodium-dependent phosphate transporters in the renal tubules, and also by inhibiting conversion of 25(OH)D to 1,25(OH)₂D₃ by the kidney, which in turn causes reduced calcium and phosphate absorption from the gut.

**Clinical features**

The presentation is with symptoms and signs of rickets during childhood that do not respond to vitamin D supplementation. In adults, hypophosphataemic rickets may be accompanied by dental abscesses, and by bone and joint pain due to the development of an enthesopathy.

**Investigations**

The diagnosis can be confirmed by the finding of low serum phosphate levels and a reduction in tubular reabsorption of phosphate. Serum levels of vitamin D are normal and PTH is normal or elevated. Serum concentrations of FGF23 are markedly elevated. The causal mutations can be identified by genetic testing.

**Management**

The aim of treatment is to ameliorate symptoms, restore normal growth and maintain serum phosphate levels within the reference range. Traditionally, treatment has been with phosphate supplements (1–4 g daily) and alfacalcidol (1–2 μg daily) or calcitriol (0.5–1.5 μg daily), with the aim of promoting intestinal calcium and phosphate absorption. Levels of calcium and phosphate, as well as renal function, should be monitored regularly and the doses of phosphate and vitamin D metabolites carefully titrated to maintain serum phosphate within the normal range, but avoid hypercalcaemia. Burolusumab is a neutralising antibody to FGF23 which can reverse the biochemical abnormalities in hereditary hypophosphataemic rickets. It is currently licensed for the treatment of XLH in children where it has been shown to be superior to standard therapy with phosphate supplements and active vitamin D metabolites at healing rickets. It is also effective at reversing hypophosphataemia in adults, and trials are currently in progress to examine the effects on clinical outcome of the disease in adults.

**Tumour-induced osteomalacia**

This is a rare syndrome caused by over-production of FGF23 by mesenchymal tumours. The presentation is with severe osteomalacia and hypophosphataemia in an adult patient with no obvious predisposing risk factor for vitamin D deficiency. Biochemical findings are as described for hereditary hypophosphataemic rickets. The underlying tumour can be difficult to find and multiple modality imaging with whole-body MRI, CT and somatostatin or gallium-68 DOTATATE scintigraphy is often needed. Options for medical management include phosphate supplements and active vitamin D metabolites or burolusumab, but the treatment of choice is surgical resection of the primary tumour, which is curative.

**Hypophosphatasia**

Hypophosphatasia is an autosomal recessive disorder caused by loss-of-function mutations in the TNALP gene, which results in accumulation of pyrophosphate and inhibition of bone mineralisation. The typical presentation is with severe intractable rickets during infancy, sometimes in association with seizures. Investigations show low or undetectable levels of serum ALP, but normal levels of calcium, phosphate, PTH and vitamin D metabolites. Urine excretion of pyridoxal 5’-phosphate and phosphoethanolamine (substrates for ALP) is increased. In severely affected patients, remarkable therapeutic responses have been obtained with recombinant ALP therapy (asfotase alfa), which is curative. Heterozygous carriers of mutation in TNALP may present in adulthood with osteoporosis, fractures and low ALP values. The best mode of treatment for these patients remains to be determined.

**Other causes of osteomalacia**

These are summarised in Box 26.75. Osteomalacia may occur as a component of renal osteodystrophy in patients with chronic kidney disease. The mechanism is reduced conversion of 25(OH)D into the active metabolite 1,25(OH)₂D₃ by the failing kidney. Aluminium intoxication is now rare due to reduced use of aluminium-containing phosphate binders and removal of aluminium from the water supplies used in dialysis. If aluminium intoxication is suspected, the diagnosis can be confirmed by demonstration of aluminium at the calcification front in a bone biopsy. Osteomalacia due to bisphosphonates has mostly been described in patients with Paget’s disease who are receiving etidronate and high-dose pamidronate. It is usually asymptomatic and healing occurs when treatment is stopped. Excessive fluoride intake causes osteomalacia due to direct inhibition of mineralisation and is common in parts of the world where there is a high fluoride content in drinking water. The condition reverses when fluoride intake is reduced.
Paget’s disease of bone

Paget’s disease of bone (PDB) is characterised by focal areas of increased and disorganised bone remodelling involving one or more skeletal sites. The disease is common in the UK, affecting about 1% of those aged above 55, and in other countries in Europe. It is rare in Scandinavia and Asia. The prevalence doubles each decade from the age of 60 onwards and affects up to 8% of the UK population by the age of 85.

Pathophysiology

The primary abnormality is increased osteoclastic bone resorption, accompanied by marrow fibrosis, increased vascularity of bone and increased, but disorganised, bone formation. Osteoclasts in PDB are greater in number and unusually large, containing characteristic nuclear inclusion bodies. Genetic factors are important and mutations in the SQSTM1 gene are a common cause of classical PDB. The presence of nuclear inclusion bodies in osteoclasts has fuelled speculation that PDB might be caused by a slow virus infection, but this remains unproven. Biomechanical factors may influence which bones are affected, as PDB often starts at sites of muscle insertions into bone and, in some cases, localises to bones or limbs that have been subjected to repetitive trauma or overuse. Involvement of subchondral bone can compromise the joint and predispose to OA. The prevalence of PDB has fallen in many countries over recent decades, suggesting that environmental factors play a role, but their identity remains unclear.

Clinical features

The axial skeleton is predominantly affected and common sites of involvement are the pelvis, femur, tibia, lumbar spine, skull and scapula. The most common presentation is with bone pain localised to an affected site, but bone deformity, deafness and pathological fractures may also be presenting features. Many patients are asymptomatic and in about 20% of cases the diagnosis is made on the basis of an X-ray or blood test performed for another reason. Clinical signs include bone deformity and expansion, and increased warmth over an affected bone. Neurological problems, such as deafness, cranial nerve defects, nerve root pain, spinal cord compression and spinal stenosis, may occur due to enlargement of affected bones and encroachment on the spinal cord and nerve foramina. Surprisingly, deafness is seldom due to compression of the auditory nerve, but instead is conductive in nature due to osteosclerosis of the temporal bone. The increased vascularity of pagetic bone can very rarely precipitate high-output cardiac failure in older patients with limited cardiac reserve. Osteosarcoma is an unusual but serious complication that presents with increasing pain and swelling of an affected site.

Investigations

The characteristic features are an isolated elevation in ALP and bone expansion on X-rays, with alternating areas of radiolucency and osteosclerosis (Fig. 26.64A). Levels of ALP can be normal if only a single bone is affected. The best way of identifying affected sites is a radiophosphate bone scan, which shows increased uptake in affected bones (Fig. 26.64B). If the bone scan is positive, X-rays should be taken to confirm the diagnosis. Bone biopsy is not usually required, but may help to exclude osteosclerotic metastases in cases of diagnostic uncertainty.

Management

The main indication for treatment with inhibitors of bone resorption is bone pain, which is thought to be due to increased metabolic activity (Box 26.76). Patients should be carefully assessed to determine the cause of the pain since it can be difficult to differentiate the pain caused by increased metabolic activity of PDB from that caused by complications such as bone deformity, nerve compression symptoms and OA. Zoledronic acid is considered the treatment of choice since it is highly effective at suppressing elevated bone turnover in PDB and is most likely to give a favourable pain response. Intravenous pamidronate and oral risedronate can also be effective. If there is doubt about whether the pain is due to PDB, it can be worthwhile giving a therapeutic trial of bisphosphonate to determine whether the symptoms improve. Although there is always the possibility of a ‘placebo effect’, a positive response usually indicates that the pain was due to increased metabolic activity. Repeated courses of bisphosphonates can be given if symptoms recur. There is not any firm evidence as yet to suggest

B] Bone scintigraphy from the same patient showing intense tracer uptake in the affected bone.
Other bone diseases

Complex regional pain syndrome type 1

Complex regional pain syndrome (CRPS) type 1 is characterised by gradual onset of pain, swelling and local tenderness, usually affecting a limb extremity. It may be triggered by fracture, but can also occur in association with soft tissue injury, pregnancy and intermittent illness or can develop spontaneously. The cause is unknown, but abnormalities of the sympathetic nervous system are thought to play a pathogenic role. The affected limb is swollen and tender, and there may be evidence of regional autonomic dysfunction with abnormal sweating and changes in skin colour and temperature. The diagnosis is primarily clinical, based on the features shown in Box 8.12. Support for the diagnosis can be obtained with MRI, which shows bone marrow oedema, or radionuclide bone scan, which shows a local increase in tracer uptake. X-rays typically show localised patchy osteoporosis. Haematology, biochemistry and immunology are normal.

The aims of treatment are to control pain and encourage mobilisation. Analgesics, NSAIDs, antineuropathic agents, calcitonin, glucocorticoids, β-adrenoceptor antagonists (β-blockers), sympathectomy and bisphosphonates have all been tried, but none is particularly effective. Although some cases resolve with time, many individuals have persistent symptoms and fail to regain normal function.

Osteonecrosis

Osteonecrosis is the term used to describe death of bone due to impairment of its blood supply. The most commonly affected sites are the femoral head, humeral head, navicular and scaphoid. In some cases, the condition occurs as the result of direct trauma that interrupts the blood supply to the affected bone. This is the reason for osteonecrosis of the femoral head following fractures of the femoral neck and in patients with thrombophilia, antiphospholipid syndrome, Gaucher’s disease and haemoglobinopathies, such as sickle cell disease. Other important predisposing factors include high-dose glucocorticoid treatment, alcohol excess, SLE, HIV and radiotherapy; but in many of these conditions the pathophysiology is poorly understood. The presentation is with pain localised to the affected site, which is exacerbated by weight-bearing. The diagnosis can be confirmed by MRI, which shows evidence of subchondral necrotic bone and bone marrow oedema. X-rays are normal in the early stages, but later may show evidence of osteosclerosis and deformity of the affected bone. There is no specific treatment. Management should focus on controlling pain and encouraging mobilisation. Symptoms often improve spontaneously with time, but joint replacement may be required in patients who have persisting pain in association with significant structural damage to the affected joint.

Scheuermann’s osteochondritis

This disorder predominantly affects adolescent boys, who develop a dorsal kyphosis in association with irregular radiographic ossification of the vertebral end plates. It has a strong genetic component and may sometimes be inherited in an autosomal dominant manner. Most patients are asymptomatic, but back pain aggravated by exercise and relieved by rest may occur. Excessive exercise and heavy manual labour before epiphyseal fusion has occurred may aggravate symptoms. Management consists of advice to avoid excessive activity and provision of protective postural exercises. Rarely, corrective surgery may be required if there is severe deformity. Scheuermann’s disease can sometimes present for the first time in adulthood, when it can be confused with osteoporotic vertebral fractures. It can be differentiated from osteoporosis by the characteristic X-ray changes, which show mild wedge deformity of 3–4 adjacent vertebrae, irregularity of the vertebral end plates, and normal BMD on DXA examination.

Fibrous dysplasia

This is an acquired systemic disorder that mainly affects the skeleton and is caused by somatic mutations in the GNAS1 gene. The characteristic presentation is with bone pain and pathological fractures. Associated features include endocrine dysfunction, especially precocious puberty, and café-au-lait skin pigmentation (McCune–Albright syndrome). The diagnosis can usually be made by imaging, which shows focal, predominantly osteolytic lesions with bone expansion on X-rays (Fig. 26.65), and focal increased uptake on bone scan. The condition may cause a single (monostotic) or multiple (polyostotic) lesions. The condition can superficially resemble Paget’s disease of bone, but the earlier age of onset and pattern of involvement are usually distinctive. Very rarely, malignant change can occur and should be suspected if there is a sudden increase in pain and swelling. Management is symptomatic. Intravenous bisphosphonates are often used in an attempt to control pain, but the evidence base for their efficacy is weak. Orthopaedic surgery may be required for treatment of fracture and deformity or to prevent a pathological fracture in a weight-bearing bone. Orthopaedic surgery may be required for treatment of fracture and deformity or to prevent a pathological fracture in a weight-bearing bone. Endocrine manifestations, such as precocious puberty, may require specific treatment.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is the name given to a group of disorders characterised by severe osteoporosis and multiple fractures in infancy and childhood. Most cases are caused by mutations in the COL1A1 and COL1A2 genes, which encode the proteins that make type I collagen. These result in reduced collagen production (in mild OI) or in formation of abnormal collagen chains that are rapidly degraded (in severe OI). Mutations in several other genes have been described that can cause OI, some of which affect post-translational modification of collagen and

Fig. 26.65 Fibrous dysplasia. X-ray of the right humerus in a patient with polyostotic fibrous dysplasia showing multiple expansile osteolytic lesions and a pathological fracture in the humeral mid-shaft (arrow).
others that affect bone formation. Many patients have no family history. Some of these have new mutations whereas others may have recessive forms of the disease. The Silence classification is commonly used to grade severity. This varies from neonatal lethal OI (type II), through very severe OI with multiple fractures in infancy and childhood (types III and IV), to mild (type I), in which affected patients typically have blue sclerae. The diagnosis of OI is usually obvious clinically, based on the presentation with multiple low-trauma fractures during infancy. The disease can be mistaken for non-accidental injury in childhood and for osteoporosis in adulthood; in such cases, genetic testing can be of diagnostic value. Treatment is multidisciplinary, involving surgical reduction and fixation of fractures and correction of limb deformities, with physiotherapy and occupational therapy for rehabilitation of patients with bone deformity. Bisphosphonates are widely used in the treatment of OI, especially intra- venous pamidronate and zoledronic acid in children, but there is limited evidence for efficacy in fracture prevention.

Osteopetrosis

Osteopetrosis is the collective name given to a rare group of inherited diseases caused by failure of osteoclast function. Presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers–Schönberg disease) shows autosomal dominant inheritance and presents with bone pain, cranial nerve palsies, osteomyelitis, OA or fracture; it is sometimes detected as an incidental radiographic finding. The responsible mutations affect either the genes that regulate osteoclast differentiation (RANK, RANKL), causing ‘osteoclast-poor’ osteopetrosis, or the genes involved in bone resorption, causing ‘osteoclast-rich’ osteopetrosis. These include mutations in the TCIRG1 gene, which encodes a component of the osteoclast proton pump, and mutations in the CLCN7 gene, which encodes the osteoclast chloride pump. The most effective treatment is bone marrow transplantation that can provide a source of osteoclasts that resorb bone normally, but this is not effective in patients with RANKL mutations. Medical management has generally limited efficacy, but IFN\(\gamma\) treatment may improve blood counts and reduce the frequency of infections.

Sclerosing bone dysplasias

These are rare diseases characterised by osteosclerosis and increased bone formation. Van Buchem disease and sclerosteosis are recessive disorders caused by loss-of-function mutations in the SOST gene, which normally suppresses bone formation (see Fig. 26.3). The resulting lack of functional sclerostin causes increased bone formation and bone overgrowth, leading to enlargement of the cranial and jaw, tall stature and cranial nerve palsies. There is no effective treatment. High bone mass syndrome is a benign disorder caused by mutations in the LRP4 or LRPPR gene, which is characterised by unusually high bone density. The mutations render the LRP receptors resistant to the inhibitory effects of SOST. Most patients are asymptomatic, but bone overgrowth in the palate (torus palatinus) and enlargement of the mandible can occur in later life. Treatment is not usually required. Camurati–Engelmann disease is an autosomal dominant condition caused by gain of function in the TGFBR1 gene. It presents with bone pain, muscle weakness and osteosclerosis mainly affecting the diaphysis of long bones. Glucocorticoids can help the bone pain, although usually analgesics are also required.

Bone and joint tumours

Primary tumours of bones and joints are rare, have a peak incidence in childhood and adolescence, and can be benign or malignant.

Rheumatological involvement in other diseases

Many systemic diseases can affect the locomotor system and many drugs may cause adverse musculoskeletal effects (Box 26.79). The most
common examples are described here. Bone disease may also occur in sarcoidosis, haemophilia and sickle-cell anaemia.

Malignant disease

Malignant disease can cause a variety of non-metastatic musculoskeletal problems (Box 26.78). One of the most striking is hypertrophic pulmonary osteoarthropathy (HPOA), characterised by clubbing and painful swelling of the limbs, periosteal new bone formation and arthralgia/arthritis. The most common causes are bronchial carcinoma and mesothelioma. Bone scans show increased periosteal uptake before new bone is apparent on X-ray. The course follows that of the underlying malignancy and HPOA resolves if this is cured.

Endocrine disease

Hypothyroidism may present with carpal tunnel syndrome or, rarely, with painful, symmetrical proximal myopathy and muscle hypertrophy. Both resolve with levothyroxine replacement. Primary hyperparathyroidism is associated with osteoporosis and also predisposes to CPPD disease and to calcific periarthritis, especially in patients with renal disease.

Diabetes mellitus commonly causes diabetic cheirarthropy, characterised by tightening of skin and periarticular structures, causing flexion deformities of the fingers that may be painful. Diabetic osteopathy presents as foetal pain with radiographic progression from osteopenia to complete osteolysis of the phalanges and metatarsals. Diabetes also predisposes to osteoporosis, fragility fractures, adhesive capsulitis, Dupuytren’s contracture, osteomyelitis, septic arthritis and Charcot’s joints.

Acromegaly can be associated with mechanical back pain, with normal or excessive movement; carpal tunnel syndrome; Raynaud’s syndrome and an arthropy (50%). This arthropy mainly affects the large joints and has clinical similarities to OA, but with a normal or increased range of movement. X-rays may show widening of joint spaces, squaring of bone ends, generalised osteopenia and tufting of terminal phalanges. It does not improve with treatment of the acromegaly and is an important cause of reduced quality of life in affected individuals.

Haematological disease

Haemochromatosis is complicated by an arthropy in about 50% of cases. It typically presents between the ages of 40 and 50 and may predate other features of the disease. The small joints of the hands and wrists are typically affected but the hips, shoulders and knees may also be involved. The X-ray changes resemble OA, but cysts are often multiple and prominent with little osteocyte formation. Involvement of the radiocarpal and MCP joints may occur, which is unusual in primary OA, and about 30% have CPPD. Treatment of the haemochromatosis does not influence the arthropy and management is as described for OA. Haemophilia can be complicated by haemarthrosis, which, if recurrent, can result in the development of secondary OA. Sickle-cell disease may be associated with bone pain, osteonecrosis and osteomyelitis. Thalassaemia may be complicated by bone deformity, especially affecting the craniofacial bones, and by osteoporosis.

Neurological disease

Neurological disease may result in rapidly destructive arthritis of joints, first described by Charcot in association with syphilis. The cause is incompletely understood, but may involve repetitive trauma as the result of sensory loss and altered blood flow secondary to impaired sympathetic nervous system control. The main predisposing diseases and sites of involvement are:

- diabetic neuropathy (hindfoot)
- syringomyelia (shoulder, elbow, wrist)
- leprosy (hands, feet)
- tabes dorsalis (knees, spine).

The presentation is with subacute or chronic monoarthritis. Pain can occur, especially at the onset, but once the join is severely deranged, pain is often minimal and signs become disproportionately greater than symptoms. The joint is often grossly swollen, with effusion, crepitus, marked instability and deformity, but usually no increased warmth. X-rays show disorganisation of normal joint architecture and often multiple loose bodies (Fig. 26.66), and either no (atrophic) or gross (hypertrophic) new bone formation. Management principally involves orthoses and occasionally arthrodesis.

Miscellaneous conditions

Anterior tibial compartment syndrome

This is characterised by severe pain in the front of the lower leg, aggravated by exercise and relieved by rest. Symptoms result from fascial compression of the muscles in the anterior tibial compartment and may be associated with foot drop. Treatment is by surgical decompression.

Carpal tunnel syndrome

This is a common nerve entrapment syndrome caused by compression of the median nerve at the wrist. It presents with numbness, tingling
and pain in a median nerve distribution. The most common causes are hypothyroidism, diabetes mellitus, rheumatoid arthritis, obesity and pregnancy (especially in the third trimester). In some patients, no underlying cause may be identified. Carpal tunnel syndrome often responds to treatment of the underlying condition, but other options include local glucocorticoid injections and surgical decompression.

### Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a common disorder, affecting 10% of men and 8% of women over the age of 65, but its prevalence increases further with age and is associated with obesity, hypertension and type 2 diabetes mellitus. It is characterised by syndesmophytes and florid new bone formation along the anterolateral aspect of contiguous vertebral bodies (Fig. 26.67). DISH is distinguished from lumbar spondylolisthesis by the absence of disc space narrowing and marginal vertebral body sclerosis, and from ankylosing spondylitis by the absence of sacroiliitis or apophyseal joint fusion. It is usually an asymptomatic radiographic finding, but can cause back pain or pain at peripheral sites, such as the heel, in association with entheseophyte formation.

### Dupuytren’s contracture

Dupuytren’s contracture is characterised by fibrosis and contracture of the superficial palmar fascia of the hands. The patient is unable to extend the fingers fully and there is puckering of the skin with palpable nodules. The ring and little fingers are usually the first and worst affected. Dupuytren’s contracture is usually painless, but causes problems due to limitation of hand function and snaggling of the curled fingers in pockets. It is age-related, usually bilateral and more common in men. There is a strong genetic component and sometimes may be familial, with dominant inheritance. The condition can be associated with plantar fibromatosis, Peyronie’s disease, alcohol misuse and chronic vibration injury. It is very slowly progressive. Often no treatment is required, but it can be treated medically by local injections of collagenase or surgically by fasciectomy if symptoms are troublesome.

### Joint hypermobility

Joint hypermobility is caused by increased laxity of connective tissues. It is commonly observed in a number of hereditary conditions including: Marfan syndrome, which arises from mutations in the FBN1 gene; osteogenesis imperfecta and Ehlers–Danlos syndrome types I, II and IV, caused by mutations in the COL3A1, COL5A1 and COL5A2 genes.

Hypermobile = a score of 6 or more points out of a possible 9 for epidemiological studies, or 4 or more points (with arthralgia in four or more joints) for a clinical diagnosis of the benign joint hypermobility syndrome.

The term hypermobile Ehlers–Danlos syndrome (hEDS), which is also known as EDS type III, is used to describe a polygenic form of joint hypermobility. Patients with this condition have hypermobile joints in combination with a range of symptoms such as chronic joint and ligamentous pain, fibromyalgia-like symptoms, recurrent dislocations, easy bruising, abdominal symptoms, insensitivity to local anaesthetic, mitral valve prolapse and postural orthostatic tachycardia syndrome (POTS), in which there is dizziness, hypotension and an increased heart rate on standing. The diagnosis of hEDS can be made if the modified Beighton score is 4 or above (Box 26.60) in the presence of one or more of the above clinical features. It is useful to distinguish hEDS from the milder hypermobility spectrum disorder (HSD), which is the name given to the syndrome where joint hypermobility is accompanied by some, but not all, features of hEDS.

### Inclusion body myositis

Inclusion body myositis (IBM) is the most frequent primary myopathy in middle age and after. It is characterised by slowly progressive muscle weakness and atrophy, with pathological changes of inflammation, degeneration and mitochondrial abnormality in affected muscle fibres. IBM typically presents with distal muscle weakness. In time, muscles atrophy. Investigation is the same as for polymyositis. There is typically a slightly elevated creatine kinase and myopathic changes on EMG.
Muscle biopsy shows abnormal fibres containing rimmed vacuoles and filamentous inclusions in the nucleus and cytoplasm. Therapeutic response to glucocorticoids and immunosuppressants is poor. There is anecdotal report of efficacy with IVlg, but trial evidence is lacking.

### Pigmented villonodular synovitis

Pigmented villonodular synovitis is an uncommon proliferative disorder of synovium, which typically affects young adults. It is caused by a somatic chromosomal translocation in synovial cells that places the CSF1 gene downstream of the COL6A3 gene promoter. The result is local over-production of M-CSF, which causes accumulation of macrophages in the joint. The presentation is with joint swelling, limitation of movement and local discomfort. The diagnosis can be confirmed by MRI or synovial biopsy. Treatment is by surgical or radiation synovectomy.

### Scoliosis

Scoliosis is characterised by an abnormal lateral curvature of the spine with a radius of greater than 10 degrees. Scoliosis may be secondary to known disorders or idiopathic. In about 20% of cases, scoliosis is secondary to a neuromuscular disorder, such as muscular dystrophy, cerebral palsy or neurofibromatosis. It may also occur in association with hereditary connective tissue diseases, such as Marfan syndrome. Scoliosis may also develop in later life, usually as a result of structural changes in the spine from degenerative change. The term idiopathic scoliosis is used to described the remaining cases where there is no obvious cause. In fact, there is strong evidence from twin studies that idiopathic scoliosis is genetically mediated, in keeping with the finding that it is evident during childhood or adolescence. It is often asymptomatic, but it can persist into adulthood and may become symptomatic, associated with evolving degenerative changes.

The diagnosis of scoliosis can be made clinically by physical examination and confirmed by X-ray. External bracing and/or surgical intervention are considered in adolescents with severe deformities to correct deformity or prevent progression, but the evidence base is poor. In adulthood, treatment is symptomatic in nature with analgesics, NSAIDs or antineuropathic medications.

### Spondylosis

Spondylosis describes a break in the integrity of the vertebral neural arch. The principal cause is an acquired defect in the pars interarticularis due to a fracture, mainly seen in gymnasts, dancers and runners, in whom it is an important cause of back pain. Spondylolisthesis describes the condition in which a defect causes slippage of a vertebra on the one below. This may be congenital, post-traumatic or degenerative. Rarely, it can result from metastatic destruction of the posterior elements. Uncomplicated spondylosis does not cause symptoms, but spondylolisthesis can lead to low back pain aggravated by standing and walking. Occasionally, symptoms of nerve root or spinal compression may occur. The diagnosis can be made on oblique X-rays of the lumbar spine, but MRI may be required if there is neurological involvement. Advice on posture and muscle-strengthening exercises is required in mild cases. Surgical fusion is indicated for severe and recurrent low back pain. Surgical decompression is mandatory prior to fusion in patients with significant lumbar stenosis or symptoms of cauda equina compression.

### Chronic non-infectious osteomyelitis

Chronic non-infectious osteomyelitis (CNO) is characterised by pain, swelling and osteosclerosis of affected bones. It may target a single bone or multiple bones when it is called chronic recurrent multifocal osteomyelitis (CROMO). The conditions can occur in the absence of other features or be part of the synovitis–acne–pustulosis–hyperostosis–ostitis (SAPHO) syndrome. These disorders often target the clavicles and bones of the anterior chest wall but other bones may be affected, including the mandible and lower limb bones. SAPHO syndrome may be part of a spectrum of autoinflammatory bone disease that includes chronic recurrent (sterile) multifocal osteomyelitis in children and adolescents. Other features of SAPHO include a pustular rash affecting the palms and soles of the feet, enthesitis, spondylodiscitis, sacroiliitis and synovitis of peripheral joints. These disorders tend to present in children or young adults.

Radiouclide bone scans show increased uptake in affected bones with osteosclerosis and bone expansion on X-rays and CT scans. Various treatments have been used, including glucocorticoids, DMARDs, bisphosphonates, anakinra and anti-TNF-α, with most success arising from biologic use. The cause is unknown, but has been suggested to be an autoinflammatory process triggered by a micro-organism.

### Trigger finger

This occurs as the result of stenosing tenosynovitis in the flexor tendon sheath, with intermittent locking of the finger in flexion. It can arise spontaneously or in association with inflammatory diseases such as RA. Symptoms usually respond to local glucocorticoid injections, but surgical decompression is occasionally required.

Multiple Choice Questions

26.1. Which of the following statements about classical disease modifying anti-rheumatic drugs (cDMARDs) are true?
A. Leflunomide has a short half-life and clears from the body quickly when it is stopped
B. Sulfasalazine stains contact lenses yellow
C. A patient’s thiopurine S-methyltransferase (TPMT) genetic polymorphism should be checked before prescribing mycophenolate mofetil
D. Systemic glucocorticoids can cause a rebound psoriasis flare when stopped after a treatment course for psoriatic arthritis
E. Methotrexate is safe to take throughout pregnancy

Answer: B and D.

A is False – leflunomide has a long half-life and takes many months to clear from the body when stopped. Excretion of leflunomide can be expedited by a short course of cholestyramine. B is True – urine can be yellow-stained also. C is False – TPMT is checked before azathioprine is prescribed. 1 in 300 people have a homozygous TPMT allele genotype which leads to very slow drug metabolism, which increases the risk of azathioprine toxicity markedly. D is True. E is False – methotrexate needs to be stopped 3 months before conception.

26.2. Which of the following statements about biologic disease-modifying anti-rheumatic drugs (bDMARDs/"biologics") are true?
A. Biologics are carcinogenic
B. Ustekinumab is an antibody to p40, which is a subunit shared by the cytokines IL-23 and IL-12. It acts as an inhibitor of both IL-12 and IL-23 signalling and is indicated in adults with psoriatic arthritis
C. Like all anti-TNF-α therapies, etanercept can be used in axial spondyloarthritides patients to also control associated Crohn’s disease
D. All anti-TNF-α bDMARDs should be stopped in the third trimester since they all cross the placenta and can cause immunosuppression in the neonate
E. In ANCA-positive vasculitis, a single cycle of rituximab (anti-CD20) treatment may last for up to 18 months

Answer: A and E.

A is False – biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. B is True. C is False – anti-TNF-α therapies generally are effective in enteropathic arthritis, but etanercept should be avoided as it has no efficacy in IBD. D is False – most should be stopped but an exception is certolizumab, which does not cross the placenta and can be used safely throughout pregnancy. E is True.

26.3. In general, infections that affect the musculoskeletal system are not common but their effects can be severe. Which of the following statements about infections are true?
A. Overall the risk of death from septic arthritis is 1%
B. Gonococcal septic arthritis is generally a polyarthritis
C. Diabetes is a particularly important risk factor for osteomyelitis, accounting for about 30% of cases
D. Where TB of a joint is suspected fluid should be drawn and analysed by microscopy, culture and PCR
E. Spine involvement (Poncet’s disease) is rare in cases of musculoskeletal TB

Answer: C and D.

A is False – overall, septic arthritis still has a mortality of about 10% despite advances in antimicrobial therapy. B is False – gonococcal infection can present with a migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. C is True. D is True – culture of synovial fluid is positive in between 20% and 40% of cases, but examination of synovial fluid or synovial tissue by PCR can yield the diagnosis more rapidly, with positive results in more than 95% of culture-positive cases and 50%–60% of culture-negative cases. E is False – Poncet’s disease occurs in about 50% of cases of musculoskeletal TB.

Clinical examination in skin disease

1. Distribution of rash
   - Symmetrical vs asymmetrical
   - Proximal vs distal vs facial
   - Localised vs widespread

2. If symmetrical
   - Extensor, e.g. psoriasis
   - Flexor, e.g. eczema

3. Involvement of hands, including nail folds and finger webs

4. Nail involvement
   - Psoriatic changes in nails and peri-ungual involvement

5. Involvement of axillae/groins
   - e.g. hidradenitis suppurativa

6. Morphology of rash
   - Monomorphic or polymorphic

7. Overall description of individual lesions
   - Discrete, grouped, confluent, reticulate (lace-like), linear

8. Detailed morphology of individual lesions
   - Use a magnifying lens in good lighting to assist
   - Use correct terminology (see definitions throughout text)

9. Examination of scalp
   - Hair loss
   - Scalp changes

10. Involvement of face
    - Central
    - Hairline
    - Cheeks and nasal bridge: ‘butterfly’ distribution
    - Sparing of light-protected sites, e.g. behind ears, under chin

11. Eye involvement
    - e.g. Conjunctivitis/blepharitis in rosacea or eyelash loss in alopecia areata

12. Oral and genital involvement
    - Nail involvement
    - Psoriatic changes in nails and peri-ungual involvement

13. Joint involvement
    - e.g. Psoriatic arthritis

14. General medical examination
    - Including lymph nodes and other systems as indicated

Observation
The patient must be undressed, with make-up and dressings removed, and examined in good lighting. Consider the following:
- Age
- General health
- Distress
- Scratching

Magnifying lens image of benign naevus

Palmoplantar pustulosis

Alopecia areata

Reticulate (lacy) network on buccal mucosa in lichen planus. May also be genital involvement

Arthritis, plaque psoriasis and psoriatic nail dystrophy
It is tempting to examine the skin first. This is a mistake; take a history, then examine the skin and the rest of the patient.

1. History-taking
   - Onset and course
   - Exacerbating/relieving factors
   - Past history of skin disease, atopy or autoimmune disease
   - Social history, occupation, recreation
   - Psychological impact, gauged by health-related life quality indices

2. Drug/allergy history
   - Always take a detailed drug and allergy history
   - Include all systemic and topical drugs, and over-the-counter preparations
   - Is it a rash or a lesion?
   - Distribution and morphology important for rash

3. Examination of skin
   - Examine skin, hair, nails and mucous membranes
   - Use of a magnifying lens and/or dermatoscope may be invaluable
   - Site, size and detailed morphology of a lesion are essential factors to elicit

4. Closer inspection
   - General examination, incl. peripheral lymph nodes, may be indicated/important
   - Skin diseases may have systemic features (e.g. cardiovascular disease in psoriasis); many systemic diseases have dermatological features (e.g. diabetes)

5. General examination
   - General examination, incl. peripheral lymph nodes, may be indicated/important
   - Skin diseases may have systemic features (e.g. cardiovascular disease in psoriasis); many systemic diseases have dermatological features (e.g. diabetes)

6. Define type of lesion using correct terminology
   Helps in differential diagnosis and allows colleagues to visualise the process. Other definitions are provided in the chapter.

- Macule/patch
  - Macule: circumscribed flat area of colour change ≤ 1 cm diameter; patch: > 1 cm diameter
- Papule
  - Discrete elevation ≤ 1 cm diameter
- Nodule
  - Like papule but deeper (into dermis or subcutaneous layer), > 1 cm diameter
- Plaque
  - Raised area > 1 cm diameter with flat top

- Vesicle
  - Small (≤ 1 cm diameter) fluid-filled blister
- Blisters/bullae
  - Large (> 1 cm diameter) fluid-filled blister
- Pustule
  - Visible accumulation of pus in blister
- Petechiae/purpura
  - Petechiae: tiny macules due to extravascular blood in dermis; purpura: larger, may be palpable

7. Score activity
   Tools for objective assessment of disease severity, such as the Psoriasis Area and Severity Index (PASI), are important in assessing severity and treatment responses.

   - Four body parts are each scored individually
   - Each of the four body parts is scored:
     - Redness (erythema)  0–4
     - Thickness (induration)  0–4
     - Scaling (desquamation)  0–4

   - The area of each involved body part is scored:
     - 0% 1
     - < 10% 2
     - 10–29% 3
     - 30–49% 4
     - 50–69% 5
     - 70–89% 6
     - 90–100%

   To find the PASI score, add together: (A) Sum for each part × (B) % of that part involved × (C) % weighting of that body part

   Minimum = 0; maximum = 72
Diseases affecting the skin are common, and important because the absence of normal skin function, as well as sometimes being life-threatening, can severely impair quality of life. This may be exacerbated by the fact that people with skin disease can suffer the effects of stigma, often brought about by the ill-informed understanding of others with respect to skin diseases, particularly as regards visually disfiguring skin changes or the belief that they are contagious.

Skin diseases affect all ages and there are more than 2000 different types and presentations. Assessment of the skin is valuable in the management of anyone presenting with a medical problem and, conversely, assessment of the other body systems is important when managing primary skin diseases. This chapter concentrates on common skin diseases and those that are important components of general medical conditions. Skin infections, including those related to the human immunodeficiency virus (HIV), tuberculosis, leprosy (Hansen’s disease) and syphilis, are also discussed in Chapters 14, 17, 13 and 15, respectively.

### Functional anatomy and physiology

The skin covers just under 2 m² in the average adult. The outer layer is the epidermis, a stratified squamous epithelium consisting mainly of keratinocytes. The epidermis is attached to, but separated from, the underlying dermis by the basement membrane. The dermis is less cellular and supports blood vessels, nerves and epidermal-derived appendages (hair follicles and sweat glands). Below it is the subcutis, consisting of adipose tissue.

#### Epidermis

In most sites, the epidermis is only 0.1–0.2 mm thick, except on the palms or soles, where it can extend to several millimetres. Keratinocytes make up approximately 90% of epidermal cells (Fig. 27.1). The main proliferative compartment is the basal layer. Keratinocytes synthesise a range of structural proteins, such as keratins, loricin and filaggrin (filament aggregating protein), which play key roles in maintaining the skin’s barrier function. Keratinocytes are also responsible for synthesis of vitamin D under the influence of ultraviolet B (UVB) light. There are more than 50 types of keratin and their expression varies by body site, site within the epidermis and disease state. Mutations of certain keratin genes can result in blistering disorders and ichthyosis (characterised by scale without major inflammation). As keratinocytes migrate from the basal layer, they differentiate, producing a variety of protein and lipid products. Keratinocytes undergo apoptosis in the granular layer before losing their nuclei and becoming the flattened cornocytes of the stratum corneum (keratin layer). The epidermis is a site of lipid production, and the ability of the stratum corneum to act as a hydrophobic barrier is the result of its ‘bricks and mortar’ design; dead cornocytes with highly cross-linked protein membranes (‘bricks’) lie within a metabolically active lipid layer synthesised by keratinocytes (‘mortar’). Terminal differentiation of keratinocytes relies on the keratin filaments being aggregated and this is, in part, mediated by filaggrin. Mutations of the filaggrin gene are found in ichthyosis vulgaris and in some patients with atopic eczema.

The skin is a barrier against physical stresses and infections. Cell-to-cell attachments must be able to transmit and dissipate stress, a function performed by desmosomes. Diseases that affect desmosomes, such as pemphigus, result in blistering due to keratinocyte separation.

The remaining 10% of epidermal cells are:

- **Langerhans’ cells**: these are dendritic, bone marrow-derived cells that circulate between the epidermis and local lymph nodes. Their prime function is antigen presentation to lymphocytes. Other dermal antigen-presenting dendritic cells are also present.
- **Melanocytes**: these occur predominantly in the basal layer and are of neural crest origin. They synthesise the pigment melanin from tyrosine, package it in melanosomes and transfer it to surrounding keratinocytes via their dendritic processes.
- **Merkel cells**: these occur in the basal layer and are thought to play a role in signal transduction of fine touch. Their embryological derivation is unclear.

#### Basement membrane

The basement membrane (see Fig. 27.1) is an anchor for the epidermis and allows movement of cells and nutrients between dermis and epidermis. The cell membrane of the epidermal basal cell is attached to the basement membrane via hemi-desmosomes. The lamina lucida lies immediately below the basal cell membrane and is composed predominantly of laminin. Anchoring filaments extend through the lamina lucida to attach to the lamina densa. This electron-dense layer consists mostly of type IV collagen; from it extend loops of type VII collagen, forming anchoring fibrils that fasten the basement membrane to the dermis.

#### Dermis

The dermis is vascular and supports the epidermis structurally and nutritionally. It varies in thickness from just over 1 mm on the inner forearm to 4 mm on the back. Fibroblasts are the predominant cells but others include mast cells, mononuclear phagocytes, T lymphocytes, dendritic cells, neurons and endothelial cells. The acellular part of the dermis consists mainly of collagen I and III, elastin and reticulin, synthesised by fibroblasts. Support is provided by an amorphous ground substance (mostly glycosaminoglycans, hyaluronic acid and dermanan sulphate), whose production and catabolism are altered by hormonal changes and ultraviolet radiation (UVR). Based on the pattern of collagen fibrils, the superficial dermis is termed the ‘papillary dermis’, and the deeper, coarser part is the ‘reticular dermis’.

#### Epidermal appendages

### Hair follicles

There are 3–5 million hair follicles, epidermal invaginations that develop during the second trimester. They occur throughout the skin, with the exception of palms, soles and parts of the genitalia (glabrous skin). The highest density of hair follicles is on the scalp (500–1000/cm²). Newborns are covered with fine ‘lanugo’ hairs, which are usually non-pigmented and lack a central medulla; these are subsequently replaced by vellus hair, which is similar but more likely to be pigmented. By contrast, scalp hair becomes terminal hair, which is thicker with a central medulla, is usually pigmented and grows longer. At puberty, vellus hairs in hormonally sensitive regions, such as the axillary and genital areas, become terminal hairs.

Human hairs grow in a cycle with three phases: anagen (active hair growth), catagen (transitional phase) and telogen (resting phase). The duration of each phase varies by site. On the scalp, anagen lasts several years, catagen a few days and telogen around 3 months. The length of hair at different sites reflects the differing lengths of anagen.

### Sebaceous glands

Sebaceous glands are epidermal glandular structures, usually associated with hair follicles and composed of modified keratinocytes. The cells of the sebaceous gland (sebocytes) produce a range of lipids, discharging the contents into the duct around the hair follicle. Sebum excretion is under hormonal control, with androgens increasing it (as do progesterones, to a lesser degree) and oestrogens reducing it. In animals, sebum is important for hair waterproofing but its role in humans is unclear.

### Sweat glands

Eccrine sweat glands develop in the second trimester and are also epidermal invaginations found all over the body. Their coiled ducts open directly on to the skin surface. They play a major role in
thermoregulation and, unusually, are innervated by cholinergic fibres of the sympathetic nervous system. Eccrine glands of the palms and soles are innervated differently and are activated in the ‘fight or flight’ response. Apocrine sweat glands are restricted to the axillae and the mammary and genital areas, are connected to hair follicles and are not involved in thermoregulation.

**Nails**

Fingernail growth commences at approximately 8 weeks of gestation and is complete by 32 weeks. Toenails develop slightly later. The anatomy of the nail apparatus is described later in the chapter.

**Blood vessels and nerves**

Human skin has a plentiful blood supply, arranged in superficial and deep plexuses consisting of arterioles, arterial and venous capillaries, and venules. The upper plexus in the papillary dermis communicates with the lower plexus at the junction between the dermis and the subcutis. Capillary loops arise from terminal arterioles in the horizontal papillary plexus. Blood vessels are supplied by sympathetic and parasympathetic nerves, with the relative contributions of the pathways differing by site. Sympathetic signals are important in mediating autonomic-induced vasoconstriction. The blood supply of skin is far greater than...
that required for normal skin physiology and reflects the importance of skin in thermoregulation.

### Functions of the skin

The skin has many functions, all of which can be affected by disease (Box 27.1). Skin changes associated with ageing are shown in Box 27.2.

### Investigation of skin disease

#### Magnifying glass

A hand-held or freestanding magnifying lens used under good lighting conditions (ideally daylight) is valuable for examination of the skin.

#### Wood’s light

Wood’s light is a long-wavelength UVA/short-wavelength visible (violet) light source that can be used in various ways. In hypopigmentation, such as in vitiligo, it can help in appreciating the extent of disease. In pigmented conditions, such as melasma, it can determine whether pigmentation is mainly epidermal (sharp cut-off under Wood’s lamp) or mixed epidermal and dermal (ill-defined cut-off). Wood’s lamp can also be used to help with the diagnosis of some fungal infections because of their characteristic fluorescence.

### Dermatoscopy and diascopy

Dermatoscopy (also known as dermoscopy and epiluminescence microscopy) is increasingly performed with hand-held dermoscopes. What makes dermatoscopy unique is the fact that it allows visualisation through contact of a glass plate on the instrument with a liquid film applied to the skin, or through special optics to allow non-contact dermatoscopy, enabling deeper structures to be seen without interference from reflection and refraction of light in the epidermis.

Diascopy is simply pressing on the lesion with a glass slide. This provides some of the effect of dermatoscopy, but is mainly used to remove blood from vascular lesions to make the appearance of the lesion clearer. Granulomatous skin diseases may have a characteristic appearance under diascopy, such as in lupus vulgaris (cutaneous tuberculosis), in which “apple jelly nodules” are typically seen on diascopy.

### Skin biopsy

Skin biopsy is a pivotal investigation in dermatology and can be used in a range of dermatological presentations. In the most common scenario, a skin biopsy is undertaken in order to obtain tissue on which to perform standard histopathology. However, tissue may also be subjected to a variety of staining and culture techniques, including immunostaining. Histopathological examination of skin biopsies is especially useful for tumour diagnosis. When a dermatologist or pathologist with dermatopathology expertise is involved, it can also assist in the diagnosis of inflammatory skin diseases. It is rare for histopathology of a previously undiagnosed inflammatory skin disease to provide a diagnosis on its own; clinico-pathological correlation is critical. Most biopsies are stained with haematoxylin and eosin but other stains may be useful in special situations, such as for fungal hyphae, iron or mucin. Direct immunofluorescence can also be undertaken on a fresh skin biopsy, allowing antigen visualisation using fluorescein-labelled antibodies; this is especially important in the diagnosis of autoimmune bullous disorders or connective tissue disease, such as cutaneous lupus.

### Box 27.2 Skin changes in old age

- **Chronological ageing**: due to the intrinsic ageing process.
- **Photo-ageing**: due to cumulative ultraviolet radiation (UVR) exposure and superimposed on intrinsic ageing.
- **Typical changes**: include atrophy, laxity, yellow discoloration, wrinkling, dryness, irregular pigmentation, and thinning and greying of hair.
- **Causes**: age-related alterations in structure and function of the skin, cumulative effects of environmental insults, especially UVR and smoking, cutaneous consequences of disease in other organ systems.
- **Consequences**: reduction in immune and inflammatory responses, reduction in absorption and clearance of topical medications, reduced healing, increased susceptibility to irritants, dermatitis, adverse drug effects (including topical glucocorticoid-induced atrophy and purpura) and diseases such as skin cancer.
Microbiology

Bacteriology

Bacterial swabs may identify a causative infective agent. However, organisms identified from the skin surface may not be the cause of the skin disease but instead may simply reflect colonization of skin that has already been damaged by a primary skin disease.

Virology

A number of techniques, including immunofluorescence and polymerase chain reaction (PCR), are available to diagnose herpes simplex or herpes zoster viruses from vesicle fluid.

Mycology

Scale, nail clippings (or scrapings of crumbly subungual hyperkeratosis) and plucked hairs can be examined by light microscopy. If potassium hydroxide and a simple light microscope are available, this can be performed in any outpatient clinic. Microbiology laboratories will also routinely undertake microscopy and culture for fungi and yeasts.

Patch testing

Patch testing is the investigation of choice for delayed, cell-mediated, type IV hypersensitivity reactions to topical agents, which clinically manifest as dermatitis. Potential allergens (see Box 27.23) are applied as patches to the back under occlusion for 48 hours, in vehicles and at concentrations that minimise false-positive and false-negative reactions. After 48 hours the patches are removed and patch-test readings are undertaken at time points of up to 7 days after patch-test application, with the most typical time point being at 96 hours. When interpreting patch test readings, it is important to determine the clinical relevance of any allergic reactions before giving avoidance advice.

Photopatch testing is similar to patch testing but investigates delayed hypersensitivity reactions to a topically applied agent (usually a sun-screen or topical non-steroidal anti-inflammatory drug (NSAID)) after the absorption of UVR. It involves applying substances in duplicate and irradiating one set with UVR (typically UVA, 5J/cm²), readings then being conducted in a similar manner to patch testing.

Prick tests and specific immunoglobulin E testing

Prick tests are used to investigate cutaneous type I (immediate) hypersensitivity reactions to various antigens such as pollen, house dust mite or dander. The skin is pricked with commercially available styllets through a dilution of the appropriate antigen solution. Alternatively, specific immunoglobulin E (IgE) levels to antigens can be measured in serum. If challenge tests are undertaken for patients with suspected allergy, these must be performed under controlled conditions due to the potential risk of triggering a severe reaction. More details of IgE testing are provided in Chapter 4.

Phototesting

Phototesting is extremely valuable in the assessment of suspected photosensitivity. The mainstay investigation is monochromator phototesting, which involves exposing the patient’s back to increasing doses of irradiation using narrow wavebands across the solar spectrum and then assessing responses at each waveband, using the minimal erythema dose (MED) as the endpoint. This is the dose required to cause just perceptible skin reddening (erythema) and is compared with values for the normal population. If a patient has reduced MEDs (develops erythema at lower doses than healthy subjects), this indicates abnormal photosensitivity. Thus, monochromator phototesting can be used to determine whether a patient is abnormally photosensitive, which wavebands are involved and how sensitive the patient is. Provocation testing can be performed with a broadband (usually UVA) source to induce rash at a test site (most useful for polymorphic light eruption) and is a helpful diagnostic test. Provocation testing to a variety of light sources, including artificial compact fluorescent lamps, may also be indicated, the latter being most relevant in patients with severe photosensitivity.

Patients who are referred for phototherapy will also commonly undergo an MED test, in which they are exposed to a series of test doses of the light source that will be used therapeutically (often narrowband UVB); the MED is determined 24 hours later (or 72–96 hours for the psoralen–ultraviolet A (PUVA) minimal phototoxic dose. This allows treatment regimens to be individualised, based on a patient’s erythemal responses. The MED can also detect abnormal photosensitivity, and represents a safety measure prior to starting a course of phototherapy.

Blood tests

Although most patients presenting with a skin problem do not need blood tests as part of their investigations, there are many systemic diseases that can present with skin features and, indeed, blood tests may also be indicated in the investigation of primary skin disease. A wide range of possible investigations may be required and some examples include haemoglobin, iron studies and thyroid function tests in puritus or hair loss; autoantibody screening if lupus is suspected; measurement of porphyrins for skin fragility and hypertrichosis; and hepatitis screening in lichen planus. These diverse examples emphasise the importance of considering an underlying systemic disease when assessing a patient with a dermatological presentation.

Imaging

Imaging techniques are not typically required but X-rays, ultrasound, magnetic resonance imaging (MRI) or computed tomography (CT) may occasionally be indicated in specific situations, such as in metastatic melanoma or in a patient presenting with a diagnosis of cutaneous sarcoid.

Presenting problems in skin disease

The major presentations in dermatology are outlined below. Detail of the underlying disorders is mostly provided in the disease-specific sections further on in the chapter.

Lumps and lesions

The term lump or lesion is typically used to describe a papule or nodule, although sometimes may refer to a macule or plaque. A new or changing lump is one of the key dermatology presentations.

Clinical assessment

Detailed history-taking and examination are essential:

- **Change:** Is the lump new or has there been a change in a pre-existing lesion? What is the nature of the change – size, colour, shape or surface change? Has change been rapid or slow? Are there other features – pain, itch, inflammation, bleeding or ulceration (definition of ‘ulcer’: an area from which the epithelium and at least the upper part of the dermis have been lost – see Fig. 27.19)?
- **Patient:** What is the patient’s age? Are they fair-skinned and freckled? Have they got multiple naevi? Has there been much sun exposure? Have they used sunbeds or lived and worked in sunny climates? Have they used photoprotection? Have they had skin cancer before or is there a family history of skin cancer? What medications are they taking? Are they immunosuppressed?
- **Site:** Is it on a sun-exposed or covered site? The scalp, face, upper limbs and back in men, and face, hands and lower legs in women, are the most chronically sun-exposed sites.
- Are there other similar lesions? These might include actinic keratoses (see Fig. 27.14) or basal cell papillomas (see Fig. 27.18).
Is there a positive family history of melanoma? A suspicious naevus in a patient with a first-degree relative with melanoma probably warrants excision.

- **Morphology:** Tenderness, size, symmetry, regularity of border, colour, surface characteristics and the presence of features such as crust (definition: dried exudate of blood or serous fluid – see Fig. 27.26), scale (definition: a flake arising from the stratum corneum; any condition with a thickened stratum corneum can cause scaling – see Fig. 27.14) and ulceration must be assessed. Stretching the skin and using a magnifying lens can be helpful, such as for detecting the raised, peered edge of a basal cell carcinoma (see Fig. 27.12).
- **Dermatoscopy:** This can be used to detect the presence of abnormal vessels, such as in basal cell carcinoma or the characteristic keratin cysts in basal cell papillomas. It is invaluable for assessing pigmented and vascular lesions (Fig. 27.2).

**Is it a melanocytic naevus or a malignant melanoma?**
This is a common clinical scenario and one that it is critical to resolve correctly.

- The precise nature of the change should be determined (as above). Listen to the patient and pay attention to subtle changes, as people know their skin well.
- If the patient has other pigmented lesions, then these should be examined too, as they may be informative. For example, if the presenting lesion looks different from the others, then suspicion of melanoma is increased; conversely, if the patient has multiple basal cell papillomas, this may be reassuring – although do not be falsely reassured.
- Is there a positive family history of melanoma? A suspicious naevus in a patient with a first-degree relative with melanoma probably warrants excision.

**Fig. 27.2 Dermatoscopy.** A Changing lesion. B Dermatoscopy highlights the abnormal pigment network and other features suggestive of melanoma. Excision biopsy confirmed the diagnosis of superficial spreading malignant melanoma (Breslow thickness 0.8 mm). C Another changing lesion. D Dermatoscopy highlights the vascular lacunae of this benign angioma and the patient was reassured.

**27.3 ABCDE features of malignant melanoma**

<table>

<td>(+ Loss of skin markings)</td>
<td></td>
</tr>
</tbody>
</table>

The ABCDE ‘rule’ is a guide to the characteristic features of melanoma (Box 27.3 and see Figs. 27.2 and 27.16), although melanomas should ideally be diagnosed before the diameter is greater than 0.5 cm. Loss of normal skin markings in a pigmented lesion may be suggestive of melanoma. Conversely, normal skin markings and fine hairs dispersed evenly over a lesion are reassuring but do not exclude melanoma. The Glasgow seven-point checklist is another useful guide:

- **major features:** change in size, shape and colour
- **minor features:** diameter >0.5 cm, inflammation, oozing, bleeding, itch or altered sensation.

Patients with one major or one minor feature should be referred for further evaluation.

**Investigations and management**
If a benign diagnosis, such as basal cell papilloma, is made on clinical grounds, then the patient can be reassured and the lesion either left or treated: for example, with cryotherapy. If there are concerns about
Clinical assessment

Clinical assessment

Important aspects of the history include:

- **Age at onset and duration of rash.** Atopic eczema often starts in early childhood and psoriasis between 15 and 40 years, and both may be chronic. Infective or drug-induced rashes are more likely to be of short duration and the latter to occur in relation to drug ingestion. Duration of individual lesions is also important, as in urticaria, for example, where lesions will come and go over short periods of time and do not persist beyond 24 hours.

- **Body site at onset and distribution.** Flexural sites are more typically involved in atopic eczema, and extensor surfaces and scalp in psoriasis. Symmetry is often indicative of an endogenous disease, such as psoriasis, whereas asymmetry is more common with exogenous causes, such as contact dermatitis or infections like herpes zoster.

- **Itch.** Eczema is usually extremely itchy and psoriasis may be less so.

- **Preceding illness and systemic symptoms.** Guttate psoriasis may be precipitated by a β-haemolytic streptococcal throat infection; almost all patients with infectious mononucleosis treated with amoxicillin will develop an erythematous maculopapular eruption; a history of chance at the site of inoculation may be elicited in a presentation of secondary syphilis; malaise and arthralgia are common in drug eruptions and vasculitis.

The morphology of the rash and the characteristics of individual lesions are important (see Box 27.4).

**Rash**

A rash is the other common presentation in dermatology. The main categories of scaly rashes are listed in Box 27.4. The most common type of rash presentation is maculopapular. Diagnosis can often be made on clinical grounds, although a biopsy may be required.

**Clinical assessment**

Important aspects of the history include:

- **Age at onset and duration of rash.** Atopic eczema often starts in early childhood and psoriasis between 15 and 40 years, and both may be chronic. Infective or drug-induced rashes are more likely to be of short duration and the latter to occur in relation to drug ingestion. Duration of individual lesions is also important, as in urticaria, for example, where lesions will come and go over short periods of time and do not persist beyond 24 hours.

- **Body site at onset and distribution.** Flexural sites are more typically involved in atopic eczema, and extensor surfaces and scalp in psoriasis. Symmetry is often indicative of an endogenous disease, such as psoriasis, whereas asymmetry is more common with exogenous causes, such as contact dermatitis or infections like herpes zoster.

- **Itch.** Eczema is usually extremely itchy and psoriasis may be less so.

- **Preceding illness and systemic symptoms.** Guttate psoriasis may be precipitated by a β-haemolytic streptococcal throat infection; almost all patients with infectious mononucleosis treated with amoxicillin will develop an erythematous maculopapular eruption; a history of chance at the site of inoculation may be elicited in a presentation of secondary syphilis; malaise and arthralgia are common in drug eruptions and vasculitis.

**Investigations and management**

It is important to have a short differential diagnosis based on clinical assessment in order to direct investigations. For example, in psoriasis, no investigations may be needed and initial management with patient counselling and topical therapies may suffice. If the diagnosis is unclear, then a diagnostic skin biopsy and other targeted investigations based on the clinical picture may be required. An initial management plan should also be implemented. For example, in a child presenting with a rash that has features suggestive of impetigo, skin and nasal swabs should be performed and, once these have been taken, topical or systemic antibiotics should be introduced, depending on clinical extent of disease, and management should be adjusted accordingly, dependent on investigation findings and clinical course. In contrast, if a patient presents with a maculopapular rash shortly after introduction of a new drug, then drug withdrawal, diagnostic biopsy, full blood count, including eosinophil count, and liver and renal function tests, in parallel with topical emollients and glucocorticoids, may be indicated.

**Blisters**

A blister is a fluid-filled collection in the skin. The term vesicle is used for small lesions and bulla for larger lesions. Blistering occurs due to loss of cell adhesion within the epidermis or subepidermal region (see Fig. 27.1). The clinical presentation depends on the site or level of blisters within the skin, which in turn reflects the underlying cause. There are a limited number of conditions that present with blisters (Box 27.5):

*Usually with mucosal involvement too.

- Intact blisters are not often seen if the split is high in the epidermis (below the stratum corneum), as the blister roof is so fragile that it ruptures easily, leaving erosions (definition: an area of skin denuded by complete or partial loss of the epidermis). This occurs in pemphigus foliaceus, staphylococcal scalded skin syndrome (see Fig. 27.21) and bullous impetigo.
- If the split is lower in the epidermis, then intact flaccid blisters and erosions may be seen, as occurs in pemphigus vulgaris and toxic epidermal necrolysis (see Fig. 27.41).
- If the split is subepidermal, then tense-roofed blisters are seen. This occurs in bullous pemphigoid (see Fig. 27.42), epidermolysis bullosa acquisita and porphyria cutanea tarda (see Fig. 27.53).
- If there are foci of separation at different levels of the epidermis, such as may occur in eczema, then multilocular bullae made up of coalescing vesicles can occur.

**Clinical assessment**

Detailed history-taking and examination are critical. A history of onset, progression, mucosal involvement, drugs and systemic symptoms should be sought. Clinical assessment of the distribution, extent and morphology of the rash should be made. The Nikolsky sign is useful: sliding lateral pressure from a finger on normal-looking epidermis can dislodge and detach the epidermis in conditions with intra-epidermal defects, such as pemphigus and toxic epidermal necrolysis. A systematic approach to diagnosis is required (Fig. 27.3).

**Investigations and management**

Investigations and initial management will be guided by the clinical presentation and differential diagnosis, and are described in more detail under the specific diseases. For example, an initial approach may include directed investigations, such as incisional diagnostic skin biopsy for histology and direct immunofluorescence, indirect immunofluorescence and other targeted blood tests or skin swabs. Management should be based on the likely diagnosis and begin in parallel with investigations, until the diagnosis is confirmed.

**Itch**

Itch describes the unpleasant sensation that leads to scratching or rubbing. The terms ‘itch’ and ‘pruritus’ are synonymous; however, ‘pruritus’ is often used when itch is generalised. Itch can arise from primary cutaneous disease or be secondary to systemic disease, which may cause itch by central or peripheral mechanisms. Even when the mechanism is peripheral, there are not always signs of primary skin disease.

The nerve endings that signal itch are in the epidermis or near the dermo-epidermal junction. The underlying mechanisms of itch are not fully understood. Transmission is by unmyelinated slow-conducting C fibres through the spinothalamic tract to the thalamus and then the cortex. Aδ fibres also seem to be involved in transmitting signals to the spinal cord, and the heat-sensitive transient receptor potential (TRP) channels 1–4 are important. There is an inhibitory relationship between pain and itch. Scratching may relieve the symptom of itch after the sensation has ceased and this is either by stimulation of ascending sensory pathways that inhibit itch-transmitting neurons at the spinal cord (Wall’s ‘gate’ mechanism), or by direct damage to cutaneous sensory nerves.

The mechanisms of itch in most systemic diseases remain unclear. The itch of kidney disease, for example, may be mediated by circulating endogenous opioids. The clinical observation that peritoneal dialysis helps reduce itch more frequently than haemodialysis is consistent with this, with smaller molecules generally being dialysed more readily if the peritoneal membrane is used rather than a dialysis machine membrane.

**Clinical assessment**

It is important to determine whether skin changes are primary (a process in the skin causing itch) or secondary (skin changes caused by rubbing and scratching because of itch). This requires a thorough history and examination, sometimes with investigations, to exclude systemic disease. Many common primary skin disorders are associated with itch (Box 27.6). If itch is not connected with primary skin disease, other causes

*(UVB = ultraviolet B)*

Should be considered (Box 27.7). These include liver diseases (mainly cholestatic diseases, such as primary biliary cholangitis), malignancies (generalised itch may be the presenting feature of lymphoma), haematological conditions (generalised itch in chronic iron deficiency or water contact-provoked (aquagenic) intense itch in polycythaemia), endocrine diseases (including hypo- and hyperthyroidism), chronic kidney disease (in which severity of itch is not always clearly associated with plasma creatinine concentration) and psychogenic causes (such as in "delusions of infestation"). Itch is common in pregnancy and may be due to one of the pregnancy-specific dermatoses. Making a correct diagnosis is particularly important in pregnancy, as some disorders can be associated with increased fetal risk (Box 27.8).

**Investigations and management**

Investigations should be directed towards finding an underlying cause and there will be a different approach for itch with rash, as opposed to itch with no signs of primary skin disease (Fig. 27.4). If there are no signs of primary skin disease, investigations should be undertaken to exclude systemic disease or idioyncratic causes. Psychogenic itch should be considered only if organic disease has been ruled out. There are no consistently effective therapies to suppress itch, and so establishing the underlying cause is critical. If a clear-cut diagnosis cannot be made, non-specific approaches can be used for symptomatic relief. These include sedation, often with H1-receptor antihistamines, along with emollients and counter-irritants (such as topical menthol-containing preparations). UVB phototherapy is useful for generalised itch due to a variety of causes but the only randomised controlled study of efficacy is in chronic kidney disease. Other treatments include low-dose tricyclic antidepressants (probably through similar mechanisms to those involved when these drugs are used for chronic pain) and opiate antagonists. If a psychogenic itch is considered likely, antidepressants and/or cognitive behavioural therapy may be effective. Itch of any cause can be severe and its potentially major adverse effects on quality of life are not always fully appreciated. Assessments of impact on quality of life, such as Dermatology Life Quality Index (DLQI) scores, are essential.
Photosensitivity

Cutaneous photosensitivity is an abnormal response of the skin to UVR or visible radiation. The sun is the natural source but patients may also be exposed to artificial sources of UVR through the use of sunbeds and/or phototherapy. Chronic UVR exposure increases skin cancer risk and photo-ageing. Acute exposure can induce erythema (redness) as a normal response (Fig. 27.5). However, abnormal photosensitivity occurs when a patient reacts to lower doses than would normally cause a response, either with a heightened erythematous reaction or the development of a rash. Photo-aggravated skin diseases are exacerbated by sunlight but not caused by it. The main photosensitive and photo-aggravated diseases are listed in Box 27.9.

Sunlight consists mainly of visible light, and the UVR component is divided into three wavebands (Fig. 27.6), according to the Commission Internationale de l’Eclairage (CIE):

- **UVC** (200–280 nm), which is absorbed by ozone and does not reach the Earth’s surface.
- **UVB** (280–315 nm), which constitutes less than 10% of UVR exposure but is around 1000-fold more potent than UVA and so accounts for the erythemal ‘sunburning’ effects of sunlight.
- **UVA** (315–400 nm), which is the most abundant UVR component reaching the Earth’s surface.

The arbitrary division between UVB and UVA regions is more often considered to be at 320 nm by photobiologists, and the UVA region can be further subdivided into UVA2 (320–340 nm) and UVA1 (340–400 nm). UVA2 behaves biologically more like UVB, and UVA1 can be used therapeutically for several skin conditions, such as morphoea and eczema.

Patients with photosensitivity diseases can be abnormally sensitive to UVB, UVA, visible light (over 400 nm) or, commonly, a combination of wavebands. UVB is absorbed by window glass, whereas UVA and visible light are transmitted through glass.

(HLA = human leucocyte antigen; NSAIDs = non-steroidal anti-inflammatory drugs; UVA/UVB = ultraviolet A/B; UVR = ultraviolet radiation)
“hardening phenomenon”. Importantly, some conditions, such as solar urticaria, develop rapidly after sunlight exposure, whereas others, such as cutaneous lupus, can take several days to evolve.

**Investigations and management**

If photosensitivity is suspected, the patient should be referred to a specialist centre for assessment and investigation, usually involving monochromator phototesting. Other investigations will often include provocation, patch or photopatch testing and screening for lupus and the porphyrias. Rarely, investigations such as human leucocyte antigen (HLA) typing in suspected actinic prurigo, or DNA excision repair functional activity or genotyping in suspected xeroderma pigmentosum, may be required.

Management depends on the cause. If there is a phototox drug or chemical cause, this must be identified and addressed: for instance, by stopping the drug or treating the porphyria. Counselling in regard to sun avoidance is essential: keeping out of direct sun in the middle of the day, covering up with clothing, wearing hats with a wide brim and careful use of high-factor sunscreens. Paradoxically, in some conditions, particularly PLE and solar urticaria, phototherapy can be used to induce “hardening”, which is a term used to describe the process by which phototherapy cross-links structures in the skin; in these circumstances the mechanism of desensitisation is unclear.

Other approaches may be necessary, depending on disease and severity, and may include antihistamines (useful in two-thirds of patients with solar urticaria) and systemic immunosuppression (sometimes required in the immunological photodermatoses, such as chronic actinic dermatitis). Patients with photosensitivity are at risk of vitamin D deficiency due to reduced vitamin D synthesis by the skin and often require vitamin D supplements.

**Sunscreens**

Sunscreens can be divided into two categories: chemical sunscreens, which absorb specific wavelengths of UVR, and physical sunscreens, which reflect UVR and the shorter visible wavelengths (see Fig. 27.6). Sunscreens are now highly sophisticated and most offer protection against UVB and most UVA wavelengths. If a patient is abnormally photosensitive to the longer wavelengths of UVA and the visible part of the spectrum (for example, in cutaneous porphyrias and solar urticaria), then conventional sunscreens are not beneficial and specific reflectant

---

**Fig. 27.6** The electromagnetic spectrum. The action spectrum is not well defined for many conditions and, for some, is approximate and may vary between patients. The action spectrum for non-melanoma skin cancer mirrors that for erythema. The action spectrum for melanoma is not known but includes UVA and UVB. Photoprotection measures vary, depending on condition, although the mainstay always includes behavioural modification, clothing cover and appropriate sunscreen choices. (UV = ultraviolet; UVR = ultraviolet radiation)

**Fig. 27.7** Chronic actinic dermatitis. Note the sharp cut-off and sparing behind the ear in the shadow cast by the earlobe (Wilkinson’s triangle).

**Clinical assessment**

Taking a careful history is essential, as the patient may not have the rash when assessed. Seasonal pattern and distribution of rash are important. Key sites are the face (particularly nose, cheeks and forehead), top of ears, neck (Fig. 27.7), bald scalp, back of hands and forearms. Sparing is often seen under the chin and nose, behind the ears, on the upper eyelids and the distal digits – as we normally walk about with our eyes open and fingers flexed! It can be misleading if there is covered site involvement. Patients who are sensitive to UVA and visible light may be affected through clothing. These patients commonly experience perennial symptoms and may not be aware of the association with daylight exposure. Other photosensitivity diseases, such as actinic prurigo or chronic actinic dermatitis, may also involve covered sites. Sparing of habitually exposed sites, such as the face and back of hands, occurs most commonly in polymorphic light eruption (PLE) and is called the
sunscreens are required. Historically, these agents were less cosmetically acceptable due to visible light reflection, but current formulations, some of which are tinted, have reduced this problem.

Sunscreen protection levels are described by sun protection factor (SPF). This is the ratio of the dose of UVR required to produce skin erythema in the presence and absence of the sunscreen. A sunscreen of SPF20 means that it would take 20 times as long for a person to develop sunburn in the presence of the sunscreen, as compared to not using it. Therefore, SPF is really a sunburn protection factor and is not a good guide to how well a sunscreen will perform in protecting against other reactions (such as skin pain in erythropoietic protoporphyria or UVR-induced immunosuppression). SPF values are determined under experimental conditions whereas, in practice, people tend to use 25%–33% of the amount of sunscreen required to achieve the stated SPF and it is easy to be fooled into a false sense of security of believing that higher levels of sun protection will be achieved than in reality will be the case. Patient counselling is therefore important with regard to adequate application of sunscreen. Importantly, there is no such thing as a complete ‘sunblock’ as sunscreens offer, at best, partial protection and are no substitute for modifying behaviour and covering up.

### Leg ulcers

Leg ulcer is not a diagnosis, but a symptom of an underlying disease in which there is complete loss of the epidermis, leaving dermal layers exposed. Ulcers on the lower leg are frequently caused by vascular disease but there are other causes, as summarised in Box 27.10.

#### Clinical assessment

A detailed history of the onset and course of leg ulceration and predisposing conditions should be elicited. The site and surrounding skin should be assessed. Varicose veins are often present, although not inevitably. Assessment of the venous and arterial vasculature and neurological examination are critical. The site of ulceration may also help to indicate the underlying primary cause (Fig. 27.8). Full clinical examination is essential as the ulcer may be arising in the context of systemic disease, such as vasculitis.

#### Fig. 27.8 Causes of lower limb ulceration. The main types of leg ulcer tend to affect particular sites.

### Leg ulceration due to venous disease

Varicose veins, a history of deep venous thrombosis and obesity are predisposing factors. Incompetent valves in the deep and perforating veins of the lower leg result in retrograde flow of blood to the superficial system, and a rise in capillary pressure (‘venous hypertension’). Pericapillary fibrin cuffing occurs, leading to impairment of local tissue oxygenation and homeostasis.

The first symptom in venous ulceration is often heaviness of the legs, followed by oedema. Haemosiderin pigmentation, pallor and firmness of surrounding skin, and sometimes venous/gravitational eczema subsequently develop. This progresses to lipodermatosclerosis – firm induration due to fibrosis of the dermis and subcutis, which may produce the well-known ‘inverted champagne bottle’ appearance. Ulceration, often precipitated by trauma or infection, follows. Venous ulcers typically occur on the medial lower leg (Fig. 27.9).

#### Fig. 27.9 Patient with chronic venous insufficiency who has chronic venous stasis skin changes and venous ulceration. From Bradson RL, Chan L, Harrast MA. Physical medicine and rehabilitation, 4th edn. Elsevier, 2011.
Complications of venous leg ulceration include bacterial colonisation and infection, and contact allergic dermatitis to topical medications, dressings and bandages. Lipodermatosclerosis may cause lymphoedema and hyperkeratosis; rarely, a squamous cell carcinoma (SCC) may develop in a long-standing venous ulcer (Marjolin’s ulcer).

**Leg ulceration due to arterial disease**

Deep, painful, punched-out ulcers on the lower leg, especially the shin and foot and in the context of intermittent claudication, are likely to be due to arterial disease. Risk factors include smoking, hypertension, diabetes and hyperlipidaemia. The foot is cold and dusky, and the skin atrophic and hairless. Peripheral pulses are absent or reduced. In these circumstances a vascular surgical assessment should be sought urgently.

**Leg ulceration due to vasculitis**

Vasculitis can cause leg ulceration either directly through epidermal necrosis due to damage to the underlying vasculature, or indirectly due to neuropathy.

**Leg ulceration due to neuropathy**

The most common causes of neuropathic ulcers are diabetes and lacerosis. Microangiopathy also contributes to ulceration in diabetes. The ulcers occur over weight-bearing areas, such as the heel. In the presence of neuropathy, protection of skin from trauma is essential to prevent ulceration.

**Investigations**

Appropriate investigations include:

- **Full blood count** to detect anaemia and blood dyscrasias.
- **Urea and electrolytes** to assess renal function.
- **Urinalysis for glycosuria**.
- **Bacterial swab** if there is a purulent discharge, rapid extension, cellulitis, lymphangitis or sepsis. This can guide antibiotic therapy for secondary infection but pathogenic bacteria are not always the same as those identified from the ulcer surface.
- **Doppler ultrasound** to assess arterial circulation. An ankle systolic pressure to brachial systolic pressure index (ABPI) of below 0.8 suggests significant arterial disease and a vascular surgery opinion should be sought. However, arterial calcification, such as in diabetics, can produce a spuriously high ABPI. Pulse oximetry may also be useful, although ABPI is the preferred investigation if feasible.

**Management**

General advice on exercise, weight loss and smoking cessation is important in all cases. Specific management depends on making the correct diagnosis to identify the cause(s) of ulceration. Underlying factors, such as diabetes or anaemia, must be treated. Oedema must be reduced by leg elevation and, if there is no arterial compromise, graduated compression bandaging from toes to knees to enhance venous return and improve healing. Compression bandaging is effective for individuals with an ABPI of more than 0.8 but should be avoided if the ABPI is less than 0.8. If the ulcer is purulent, weak potassium permanganate soaks may help, and exudate and slough can be removed with normal saline or clean water. Dressings do not themselves heal leg ulcers, but can reduce discomfort and odour and, by reducing colonisation by potential pathogens, may reduce the frequency of secondary infection. A variety of dressings may be used, including non-adherent and absorbent (alginates, hydrogels, hydrocolloids) types. The frequency of dressing changes varies; heavily exudative ulcers may need daily dressings, whereas changes once weekly may suffice for drier ulcers. Occasionally, leeches may be used topically for ulcers with heavy adherent exudate.

Surrounding eczema should be suppressed with a topical glucocorticoid. Commonly, this is venous eczema, but there should be a low threshold for referral for patch testing, as contact allergy to topical applications is common. Systemic antibiotics are indicated only if there is evidence of infection, as opposed to colonisation. Various techniques of split-thickness grafting (such as pinch and mince grafts) may hasten healing of clean ulcers but do not reduce recurrence risk. Leg ulcers can be very persistent but with accurate diagnosis and optimal management, healing is usually achievable. Symptomatic relief, including oral analgetics and sometimes chronic pain management, is important. Once the ulcer has healed, ongoing use of compression hosiery is advised to limit the risk of recurrence.

**Abnormal pigmentation**

Loss of skin pigmentation (depigmentation), reduction in pigmentation (hypopigmentation) and increased pigmentation (hyperpigmentation) are features of a variety of disorders. A detailed history and examination, including use of a Wood’s light, are required to establish the diagnosis. Investigations will depend on the presentation. For example, microscopy of skin scrapings should be undertaken if hypopigmentation is associated with inflammation and scaling; screening for autoimmune disease may be required if vitiligo is suspected; and investigation for endocrine disease or the porphyrias may be appropriate in hyperpigmentation. Further details of the specific conditions are discussed later in this chapter.

**Hair and nail abnormalities**

Many conditions affect the skin appendages, particularly hair and nails. Conditions causing hair loss (alopecia) are listed in Box 27.31. Nail changes may be a marker for systemic disease, such as iron deficiency, or be a feature of certain skin conditions, such as psoriasis.

**Acute skin failure**

Acute skin failure is a medical emergency. Several conditions can cause widespread and acute failure of many skin functions (see Box 27.1), including thermoregulation, fluid balance control and barrier to infection. Many of these conditions involve widespread dilatation of the dermal vasculature and can provoke high-output cardiac failure; they are also associated with increased protein loss from the skin and often from the gut. Many lead to acute skin failure by causing erythroderma (erythema affecting at least 90% of the body surface area), although severe autoimmune blistering diseases and the spectrum of Stevens–Johnson syndrome/toxic epidermal necrolysis (TEN) disease can produce acute skin failure without erythroderma.

**Clinical assessment**

Detailed history-taking and full examination are required. Particular attention should be paid to drug history, chronology and history of any preceding skin disease. Eczema, psoriasis, drug eruptions and cutaneous T-cell lymphoma (Sézary syndrome) are among the diseases that can either present with, or progress to, erythroderma. Other causes include the psoriasis-like condition pityriasis rubra pilaris, and rare types of ichthyosis. Erythroderma may occur at any age and is associated with severe morbidity and significant mortality (see Fig. 27.36C). Older people are at greatest risk, especially if they have comorbidities. Erythroderma may appear suddenly or evolve slowly. In dark skin, the presence of pigmentation may mask erythema, giving a purplish hue.

Erythrodermic patients are usually systemically unwell with shivering and hypothermia, secondary to excess heat loss. However, they may also be pyrexial and unable to lose heat due to damage to sweat gland function and sweat duct occlusion. Tachycardia and hypotension may be present because of volume depletion. Peripheral oedema is common in erythroderma, owing to low albumin and high-output cardiac failure. Lymph nodes may be enlarged, either as a reaction to skin inflammation or, rarely, due to lymphomatous infiltration.
**Investigations and management**

Investigations are required to establish the underlying cause and to identify systemic involvement, such as hypalbuminamia, deranged liver and renal function and electrolyte imbalance. Skin biopsy may be necessary if the cause is unclear. Regardless of the cause, important aspects of the management of erythroderma include supportive measures to ensure adequate hydration, maintenance of core temperature and adequate nutrition. Insensible fluid loss can be many litres above normal losses. Protein may be lost directly from the skin and through the gut because of the protein-losing enteropathy that often accompanies conditions such as erythroderymic psoriasis. To reduce the risks of infection, any intravenous cannulae should be sited in peripheral veins, if possible. In the initial management of acute erythroderma, urinary catheterisation is often required (for patient comfort and accurate fluid balance monitoring) but catheters should be removed as soon as possible. Frequent application of a simple ointment emollient (such as white soft paraffin/liquid paraffin mix) is usually appropriate.

### Principles of management of skin disease

#### General measures

General measures that apply in all skin diseases include establishment of the correct diagnosis, removal of precipitating or aggravating factors, use of safe, effective treatments and consideration of the patient holistically, taking into account the impact of the disease on quality of life and the person’s support network. The psychological impact of chronic skin diseases should not be underestimated and it is important to remember that psychiatric illness can also manifest as a skin disease, such as in delusions of infestation or trichotillomania. Careful clinical assessment is essential and any management strategy must also include approaches to address the psychological well-being of the patient.

#### Topical treatments

Topical treatments are first-line therapy for most skin diseases, many of which can be treated effectively by topical agents alone. Selection of the appropriate active drug/ingredient and vehicle is essential. Ointments are preferred to creams for dry skin conditions, such as chronic eczemas, as they are more hydrating and contain fewer preservatives than creams, and so allergy risk is reduced. However, patients find creams easier to apply and so adherence may be better. Gels and lotions can be easier to use on hair-bearing sites. The molecular weight and lipid–water coefficient of a drug determine its skin penetration, with larger, water-soluble, polar molecules penetrating poorly. In skin disease, if the stratum corneum is impaired – as in eczema – increased drug absorption occurs. Occlusion under dressings also increases absorption. Drugs can be used in different potencies or concentrations, or in combination with other active ingredients, and many are available in more than one formulation. The properties of different vehicles are listed in Box 27.11. Overall, adherence to topical treatments can be problematic, so it is essential for patients to know exactly what is required of them and for regimens to be kept as simple as possible. Emollients, topical glucocorticoids and other selected key topical therapies that are widely used in a diverse range of skin conditions are detailed below. For the more disease-specific therapies, detailed descriptions are included in the disease sections.

#### Emollients

These are mainstays in the treatment of eczema, psoriasis and many other conditions, and are used to moisturise, lubricate, protect and ‘soften’ skin. They are essentially vehicles without active drug and are available in many formulations: creams, ointments, gels and bath, shower and soap substitutes. White soft paraffin is the most effective and is widely used.

#### Topical glucocorticoids

Glucocorticoids are available in a variety of formulations, potencies and strengths, most commonly as creams and ointments (Box 27.12). Selection of the correct product depends on the condition being treated, body site and duration of expected use. Mild topical glucocorticoids are used in delicate areas, such as the face or genitals, and close supervision of glucocorticoid use at these sites is required. In contrast, very potent glucocorticoids may be required under occlusion for chronic resistant disease such as nodular prurigo.

Adverse cutaneous effects of chronic glucocorticoid use include atrophy (definition: an area of thin, translucent skin caused by loss of...

epidermis, dermis or subcutaneous fat – Fig. 27.10), striae (definition: linear, atrophic, pink, purple or white bands caused by connective tissue changes – Fig. 27.10), petechiae and purpura (definition: haemorrhagic macules or papules caused by extravasated blood) and telangiectasias (definition: visible dilations of small cutaneous blood vessels – see Fig. 27.12A), increased risk of infection and systemic absorption, causing Cushigoid features and suppression of the hypothalamic–pituitary–adrenal axis. However, under-treatment with glucocorticoids is more common than over-treatment in routine clinical practice. In general, the lowest potency of glucocorticoid should be used for the shortest period to gain control of the disease; this can be achieved by initial use of a more potent glucocorticoid, with reduction in potency or frequency of application as control is gained. Tolerance or tachyphylaxis can develop with chronic use, so intermittent courses of treatment are advised. Caution is required with glucocorticoids in psoriasis, as rebound, unstable or pustular psoriasis can occur with sudden cessation of use. Nevertheless, glucocorticoids are invaluable for many sites, particularly the flexures. Topical glucocorticoids are often formulated in combination with antimicrobials, antibiotics or antifungals, and their controlled use may be appropriate in infected eczema or flexural psoriasis. Intraleisional injections of glucocorticoids can be used in a variety of indications, including nodular prurigo, keloid scar (definition of “scar”: replacement of normal structures by fibrous tissue at the site of an injury, although keloid scar describes a pathological process extending beyond the site of injury), acne cysts and alopecia areata.

27.13 Indications for dressings

- Protection
- Symptomatic relief from pain or itch
- Maintenance of direct application of topical treatment
- Possible improvement in healing time
- Reduction of exudate
- Reduction of odour

Anti-infective agents

Antiseptics should be considered before antibiotics, as they cover a wide range of organisms and help to reduce the risk of antibiotic resistance. Antibiotics can be used either for their anti-infective properties or for their anti-inflammatory properties. Topical antiviral and antifungal agents are also widely used for a range of mild skin infections.

Calcineurin inhibitors

The topical calcineurin inhibitors tacrolimus and pimecrolimus can be used to treat eczema and a variety of other conditions, through local cutaneous immunosuppression.

Immune response modifiers

Topical imiquimod was introduced for the treatment of anogenital warts but can be used for a diverse range of other skin diseases, including actinic keratosis, Bowen’s disease, basal cell carcinoma, lentigo maligna, cutaneous lupus and common and planar warts. Its mechanism of action is via stimulation of endogenous Th2 immune responses and release of cytokines, including interferon-gamma (IFN-γ). It can cause significant inflammation, requiring dose adjustments, but subclinical disease may respond to treatment.

Dressings

A “wound” covering is called a dressing. Box 27.13 shows the indications for their use. The active agent, vehicle and “wound” type should be considered. Wet lesions should be treated with wet dressings. Paste bandages can be used in conjunction with topical emollients and glucocorticoids to soothe and cool, ease pruritus and scratching, and reduce inflammation. Dressings for venous leg ulcers are described later in this chapter.

Phototherapy and photochemotherapy

Ultraviolet radiation (UVR) treatments (most commonly, narrowband ultraviolet B and psoralen–ultraviolet A (PUVA)) are used in the management of many different diseases. The best evidence for their efficacy is in psoriasis, atop eczema, vitiligo and chronic urticaria, although there is also evidence that UVB is helpful in treating generalised itch associated with chronic kidney disease and a range of other diverse skin conditions.

Psoralens are natural photosensitisers found in a number of plants. They intercalate between the strands of DNA and, on excitation with UVA, cross-link the DNA strands. Psoralens are therefore produgs that are activated only in skin that is exposed to UVA. Psoralens can also be applied topically in a bath before irradiation with UVA (bath PUVA) or can
be applied in creams or gels for localised topical PUVA. PUVA is a more complex treatment than UVB and has more adverse effects; in particular, cumulative exposure to PUVA increases the risk of skin cancer, particularly squamous cell carcinoma. Therefore, PUVA is generally used for poor responders to UVB, or in diseases such as plaque-stage cutaneous T-cell lymphoma or pityriasis rubra pilaris, where it is the phototherapy of first choice. Phototherapy or PUVA may be offered as a whole-body or localised treatment.

Longer-wavelength UVA1 (340–400 nm) is also used for several conditions, particularly the fibrosing skin diseases such as morphea, where efficacy has been shown and there is a lack of other well-proven therapies. The evidence base for its place in the management of several diseases, such as eczema, is not fully proven and availability of UVA1 is mainly through tertiary referral centres with expertise in photodermatology and phototherapy.

### Systemic therapies

General information is provided here for drugs used in a range of skin diseases; details of other drugs are provided in disease-specific sections.

#### Antibiotics

Antibiotics are widely used for their anti-infective properties, particularly for staphylococcal and streptococcal skin infections. In these indications, the correct antibiotic should be selected, based on bacterial sensitivity and patient factors. As examples, oral flucloxacillin may be indicated for clinically infected eczema, intravenous flucloxacillin for cellulitis, and clarithromycin for a patient with a staphylococcal carbuncle who is penicillin-allergic. Optimal therapeutic doses and courses must be chosen, based on local antimicrobial prescribing guidelines. Several antibiotics, such as tetracyclines, erythromycin and co-trimoxazole are used predominantly for their anti-inflammatory effects in indications such as acne vulgaris, bullous pemphigoid and pyoderma gangrenosum.

#### Antihistamines

A range of H₁ and H₂-receptor antagonists are used in dermatology. For diseases in which histamine in the skin is relevant (such as urticaria), non-sedating antihistamines should be given: for example, fexofenadine or cetirizine. For pruritic conditions such as eczema, the sedating effect of antihistamines like hydroxyzine or chlorphenamine is important. However, antihistamines are widely used in older patients for the symptom of pruritus due to a variety of causes such as xeroderma, metabolic impairment, malignancy or concomitant drugs. Sedating antihistamines should be used with caution in older patients, as they may increase the risk of falls and accidents in the home, with disastrous consequences. Careful choice of drug and dose is therefore essential. Leukotriene receptor antagonists, such as montelukast, may be added to antihistamine regimens, for additional mast cell stabilising effects.

#### Retinoids

Oral retinoids are used in a range of conditions, including acne, psoriasis and other keratinisation disorders. They promote differentiation of skin cells and have anti-inflammatory effects. Isotretinoin (13-cis-retinoic acid) is widely used for moderate to severe acne. Acitretin can be effective in psoriasis and other keratinisation disorders, such as ichthyosis, as can altretinoin (9-cis-retinoic acid) in hand and foot eczema and bexarotene in cutaneous T-cell lymphoma.

Adverse effects of retinoids include dryness of the skin and mucous membranes, abnormalities in liver function or hepatitis, increase in serum triglycerides (levels should be checked before and during therapy) and mood disturbances. Altretinoin and bexarotene can cause hypothyroidism. Systemic retinoids are teratogenic and must be prescribed along with a robust form of contraception. Females must have a negative pregnancy test before, during and after therapy, and pregnancy must be avoided for 2 months after stopping isotretinoin and 2 years after stopping acitretin.

#### Immunosuppressants

Systemic glucocorticoids, particularly prednisolone, are widely used in inflammatory skin diseases, such as eczema, immunobullous disease and connective tissue disorders. Methotrexate, azathioprine and mycophenolate mofetil are effective in eczema and psoriasis either alone or as glucocorticoid-sparing agents. Further details on the mechanism of action, adverse effects and monitoring requirements for these agents are provided in Chapter 26 (see Box 26.33). Azathioprine is an alternative immunosuppressant to methotrexate in psoriasis, but is not licensed for this indication and appears to be less effective than methotrexate. The risk of myelosuppression is greater. Dimethyl fumarate is also used off label in the treatment of psoriasis. Ciclosporin has a rapid onset of action and is effective in inducing clearance of psoriasis and eczema. Monitoring of blood pressure and renal function is required. Ciclosporin should be used only with caution after phototherapy, particularly PUVA, because of the increased risk of skin cancer. Long-term use of ciclosporin is not advised. Dapsone is an immunomodulator and may be used in diseases in which neutrophils are implicated, such as dermatitis herpetiformis. Haemolysis, methaemoglobinemia and hyperresponsiveness can occur, and monitoring is required. Hydroxychloroquine is of particular value in cutaneous lupus.

#### Biologic and other advanced therapies

Major advances in the treatment of inflammatory skin diseases have been made in recent years through increased understanding of pathophysiology, the identification of new molecular targets for drug design and the introduction of biological treatments and small molecules that target specific signalling pathways involved in the inflammatory response. Biologic treatments work by binding to and neutralising pro-inflammatory cytokines or components of their receptors whereas small molecule inhibitors target intracellular signalling pathways situated downstream of cytokine receptors.

Multiple biologics are available for the treatment of severe or treatment-resistant psoriasis. These include multiple inhibitors of tumour necrosis factor alpha (TNF-α) (adalimumab, certolizumab, etanercept and infliximab), ustekinumab, which inhibits interleukin (IL)-12 and IL-23 by binding to the p40 component of both cytokines; guselkumab, which is a specific inhibitor of IL-23; ixekizumab and secukinumab, which are inhibitors of IL-17; and brodalumab, which inhibits the IL-17 receptor (Fig. 27.11).

Dulimumab is an antibody that targets the IL-4 receptor alpha chain subunit, which is common to both IL-4 and IL-13 receptors. It has been shown to be efficacious in the treatment of severe atopic dermatitis resistant to standard therapies. Tralokinumab and lebrikizumab are specific inhibitors of IL-13 which are also showing promise in the treatment of severe atopic dermatitis but these are not yet licensed for clinical use (Box 27.14). Omalizumab, a monoclonal antibody directed against immunoglobulin E (IgE), which is used in severe asthma, also has a role in the treatment of urticaria and some patients with atopic dermatitis. Small molecule targeted synthetic immunosuppressives have also been developed. Apremilast inhibits phosphodiesterase-E4 (PDE-4) reducing cytokine production by immune cells and is used in psoriasis. Crisaborole, another PDE-4 inhibitor, is under development for the treatment of psoriasis. Baricitinib and upadacitinib, which inhibit Janus activated kinase (JAK) enzymes that are involved in signalling downstream of several cytokine receptors, are also used in psoriasis and atopic dermatitis. Rituximab, which binds to CD20 causing depletion of B cells, is used in pemphigus vulgaris. Intravenous immunoglobulin, pooled from donor plasma, may be used in the treatment of dermatomyositis and occasionally may be indicated in other dermatological diseases. More detail on the dosages, mechanism of action and adverse effects of these agents
Fig. 27.11 Biologic and targeted therapies in inflammatory skin diseases.
Biologic treatments for inflammatory rheumatic diseases work by targeting key cytokines or their receptors involved in regulating the immune response. IL = interleukin; Th = T-helper cell subtype; TNFα = tumour necrosis factor alpha; TNFβ = tumour necrosis factor beta; PDE4 = phosphodiesterase 4; JAK = Janus activated kinase; PKA = protein kinase A; STAT = signal transducers and activators of transcription; cAMP = cyclic adenosine monophosphate)

are provided in Chapter 26 (see Box 26.35). Other new treatments that are under development include: nemolizumab, which targets the IL-31 receptor and improves itching in atopic dermatitis; ponesimod and fingolimod, which target the sphingosine-1-phosphate pathway, which is involved in trafficking immune cells into the skin; fezakinumab, which inhibits IL-22, a proinflammatory cytokine implicated in the pathogenesis of psoriasis and atopic dermatitis; and tapinarof, a small molecule modulator of the aryl hydrocarbon receptor which is a transcription factor involved in regulating production of IL-17 and other cytokines in the skin. Tumour targeted kinase inhibitors and biologics directed against CTLA-4 and the programmed cell death (PD1) pathways which are used in the treatment of melanoma are discussed later in this chapter.

Dermatological surgery

Most dermatological surgical procedures are performed under local anaesthetic. Knowledge of local anatomy is essential, particularly the locations of vessels and nerves. In certain sites, such as the fingers, soles of the feet and the nose, local cutaneous nerve blocks are useful. Some sites are associated with particular risks, such as keloidal scarring on the upper trunk of young patients, unsightly scarring over the scapulae, and poor healing and risk of ulceration following procedures on the lower legs.

Excision biopsy

This involves surgical removal of the lesion followed by histological examination. The most common indication is suspicion of malignancy. The lesion and line of excision should be marked out and the margin of excision decided before the procedure. It is important to excise down to the appropriate anatomical plane. Depending on body site, a range of procedures can minimise the resulting defect. Healing by secondary intention may also achieve good cosmetic results.

Curettage

Curettage involves using a small, spoon-shaped implement (curette), not only as a definitive treatment but also to obtain histology. Curettage does not preserve tissue architecture very well, however, and it may be difficult to distinguish between dysplasia and invasive malignancy. It can be an effective treatment for basal cell papilloma, actinic keratosis, intra-epidermal carcinoma and superficial basal cell carcinoma.
Shave excision

Shave excision using local anaesthetic may be used for simple and effective treatment of raised superficial benign skin lesions affecting epidermis and upper dermis, such as benign naevi and skin tags.

Mohs’ micrographic surgery

Mohs’ micrographic surgery is employed to ensure adequate tumour excision margins, while conserving unaffected tissue. It is most commonly used for basal cell carcinoma.

Non-surgical treatments

Cryotherapy

Cryotherapy is a destructive treatment using liquid nitrogen to cause cell-wall and membrane destruction and cell death. Liquid nitrogen can be applied either with a cotton bud or, more effectively, with a spray gun. A wide variety of conditions can be treated but it is essential for the correct diagnosis to be made first, if necessary by diagnostic biopsy. Cryotherapy should not be used to treat melanocytic naevi. Benign lesions, such as viral warts and basal cell papilloma, respond well, and cryotherapy can also be effective for actinic keratosis. Bowen’s disease or superficial non-melanoma skin cancer. Malignant indications require more vigorous treatment, usually with two cycles, and this is normally carried out in secondary care. Considerable inflammation, blistering and pigmentedary change, particularly hypopigmentation, can occur. Caution is required to avoid damage to tendons and nerves, especially when using cryotherapy on digits.

Laser therapy

Laser therapy involves treatment with monochromatic light. Skin components (chromophores), such as haemoglobin and melanin, absorb specific wavelengths of electromagnetic radiation, and these wavelengths can therefore be used to destroy these targets selectively and to treat certain skin disorders. Lasers targeting haemoglobin are employed for vascular abnormalities, such as spider naevi, telangiectasias and port-wine stains, and lasers targeting melanin can treat benign pigmented disorders or pigment in tattoos or drug-induced hyperpigmentation (for example, secondary to minocycline). Melanin-targeted lasers can also be used for hair removal if the hair is pigmented. Light delivery in short pulses restricts damage to the treated site.

The carbon dioxide laser emits infrared light that is absorbed by water in tissues and can therefore be used for destructive purposes. The depth of effect can be controlled, such that the carbon dioxide laser is widely employed for resurfacing in photorejuvenation or acne scarring. Significant morbidity is associated with this destructive laser, although this may be minimised with fractionated regimens, and general anaesthesia may be required.

Photodynamic therapy

Photodynamic therapy (PDT) is widely used in dermatology, predominantly for actinic keratoses, Bowen’s disease and superficial basal cell carcinoma.

Radiotherapy and grenz (Bucky) ray therapy

Radiotherapy can be employed for several skin conditions, including non-melanoma skin cancer or lentigo maligna that is not suitable for surgical treatment, but its use in dermatology has declined. Scarring and polikiderna can occur at treated sites, although these are minimised if fractionated regimens are chosen. Superficial radiotherapy is now rarely employed to treat benign dermatoses. Even more superficial ionising radiation (grenz (Bucky) rays) can be useful for localised dermatoses that have severe effects on quality of life, if conventional treatments have been inadequate; for example, it may avoid the need for systemic immunosuppression in a patient with severe recalcitrant localised scalp psoriasis.

Skin tumours

Pathogenesis

Skin cancer is the most common malignancy in fair-skinned populations. It is subdivided into non-melanoma skin cancer (NMSC) and melanoma. NMSC is further subdivided into the most common skin cancer, basal cell carcinoma (BCC), and squamous cell carcinoma (SCC). The latter has precursor non-invasive states of intra-epithelial carcinoma (Bowen’s disease, BD) and dysplasia (actinic keratosis, AK). Melanoma is much less common than NMSC, but because of its metastatic risk it is the cause of most skin cancer deaths.

UV radiation is a complete carcinogen and is the main environmental risk factor for skin cancer, which is much more common in countries with high ambient sun exposure, such as Australia. Skin cancer risk also increases if an individual migrates to such a country when young, particularly if less than 10 years of age. Epidemiological evidence supports a close link between chronic UVR exposure and risk of SCC and AK, and a modest link between sun exposure and BCC risk. Melanoma usually arises on sites that are intermittently exposed to UVR, and episodes of sunburn and recreational sun exposure have been implicated as risk factors for melanoma. There is good evidence to show that sunbath exposure is also a risk for both melanoma and NMSC, particularly when exposure starts in adolescence and early adult life. Strategies to reduce sun exposure are therefore important for skin cancer prevention, with reliance mainly on behavioural modification, covering up and judicious sunscreen use. Indeed, there is evidence to show that sunscreen use reduces naeVis development in children, and in adults regular sunscreen use reduces the risk of AK and SCC and is likely also to have preventative roles in melanoma and BCC development.

There are identifiable genetic predispositions for some skin cancers, such as in xeroderma pigmentosum, an autosomal recessive condition caused by an inherited defect in DNA excision repair, and basal cell naevus (Gorlin) syndrome, an autosomal dominant disorder caused by loss-of-function mutations affecting the PTCH1 tumour suppressor genes, with consequent activation of the Hedgehog pathway. Interestingly, the Hedgehog pathway is also almost invariably activated in sporadic BCC, which usually contain somatic mutations in PTCH1 and less commonly in the SMO gene, which lies in the same signalling pathway. The genetics of SCC are heterogeneous and less clearly defined, with several mutations and pathways implicated, including TP53, CDKN2A/p16, NOTCH, EGFR and the MAPK signalling pathways. Interestingly, many of the mutations seen in SCC also occur in the pre-cancers AK and BD. The genetics of melanoma are discussed later in this chapter.

Cutaneous immune surveillance is also critical and immunosuppressed organ transplant recipients have a greatly increased risk of skin cancer, particularly SCC. Interestingly, patients who have received high treatment numbers of PUVA (more than 150), which is immunosuppressive, are also at increased risk of skin cancer, particularly SCC.

Although UVB can increase the risk of skin cancer, there is no evidence to date that UVB phototherapy significantly increases skin cancer risk. Likewise, there is no evidence that UVA1 phototherapy increases skin cancer risk, although ongoing vigilance is required. Ionising radiation, notably radiotherapy, thermal radiation and chemical carcinogens, such as arsenic or coal tar, can increase NMSC risk, particularly SCC. A role for oncogenic human papillomaviruses in SCC development is also implicated, particularly in immunosuppressed patients, where viral DNA is detected in more than 80% of tumours. Chronic inflammation
is a risk factor for SCC, which may arise in chronic skin ulcers, discoid lupus erythematosus or vulgaris, and the scarring genetic skin disease dystrophic epidermolysis bullosa (see Box 27.26), in which up to 50% of patients develop SCC.

## Malignant tumours

### Basal cell carcinoma

The incidence of NMSC has increased dramatically in recent decades and basal cell carcinoma (BCC) accounts for more than 70% of cases. In Europe, the ratio of BCC to SCC is 4–5:1 in immunocompetent patients. It is a malignant tumour that rarely metastasises; it is thought to derive from immature pluripotent epidermal cells and is composed of cells with similarities to basal layer epidermis and appendages. Lesions typically occur at sites of moderate sun exposure, particularly the face, and are slow-growing. The incidence increases with age and males are more commonly affected. Lesions may ulcerate and invade locally; hence the term ‘rodent ulcer’.

### Clinical features

Early BCCs usually present as pale, translucent papules or nodules, with overlying superficial telangiectatic vessels (nodular BCC). If untreated, they increase in size and ulcerate, to form a crater with a rolled, pearl edge and telangiectatic vessels (Fig. 27.12). There may be some pigmentation or a cystic component. A superficial multifocal type can occur, frequently on the trunk, and may be large (up to 10 cm in diameter); often there are multiple lesions. Superficial BCC usually presents as a red/brown plaque or patch with a raised, thread-like edge, which is often best seen by stretching the skin; this helps to distinguish it from Bowen’s disease. Less commonly, a morphoic, infiltrative BCC presents as a poorly defined, slowly enlarging, sclerotic yellow/grey plaque.

### Diagnosis and management

The diagnosis is often obvious clinically, based on the features mentioned above, although a diagnostic confirmatory biopsy may be required prior to definitive treatment. Management depends on the characteristics of the tumour and on patient factors, including comorbidities and patient wishes. Essentially, treatment will be either surgical or, in some cases, medical (Box 27.15). Surgical excision, ideally with a 4–5 mm margin, is the treatment of choice, with a cure rate of approximately 90%. Curettage and cautery may also be effective for selected lesions. Management of infiltrative morphoic BCC and/or lesions at difficult sites, such as around the eye, may require more complex techniques, such as Mohs’ micrographic surgery, to ensure adequate tumour excision margins, while conserving unaffected tissue. This involves processing of frozen sections of all margins in stages (usually on the same day) until all the tumour is removed. The procedure is time-consuming (so can be difficult for older, frail patients) and requires particular surgical and pathology skills, but is associated with the highest long-term cure rates, with 98%–99% clear at 5-year follow-up.

If a surgical approach is used for management of BCC and the primary tumour is not completely excised, re-excision may be required, although follow-up may be appropriate as not all tumours that are incompletely excised recur. However, this is not recommended for tumours at high-risk sites or for infiltrative morphoic BCC, where complete excision is advisable. Cryotherapy may be effective for BCC but can cause blistering and scarring, so is best suited to small, superficial lesions at low-risk sites.

Radiotherapy can be invaluable for large BCC lesions in frail patients but is less commonly used because of the risk of scarring.

Medical therapies can be used to treat low-risk BCC, particularly when surgery is not appropriate for a patient. Topical immunomodulators, such as imiquimod, are effective for low-risk BCC and may be particularly useful for patients who are not able to attend a hospital clinic setting but are able to apply a topical preparation at home over a 6-week period. Imiquimod usually induces a prominent inflammatory reaction and patients should be advised that dose adjustments may be required. Topical 5-fluorouracil can also be effective for low-risk small lesions of superficial BCC, although this usually provokes an intense inflammatory reaction. Intraliesional interferon-alpha2b has been used for BCC but multiple treatments and high cost preclude its regular use.

PDT is an effective treatment for low-risk, predominantly superficial BCC, as well as AK and BD. Usually, topical porphyrin PDT is employed, which involves application of a porphyrin prodrug to the lesion to be treated. The prodrug is taken up and converted by the cell’s haem cycle to protoporphyrin IX, a photosensitiser. This is

---

**Box 27.15 Management of non-melanoma skin cancer and pre-cancer**

**Basal cell carcinoma**

- Excision results in the lowest recurrence rates
- Mohs’ micrographic surgery is effective for high-risk BCC
- Medical treatments are often appropriate for low-risk superficial tumours in patients with comorbidities
- Cryotherapy and topical 5-fluorouracil can be used for superficial BCC
- Topical photodynamic therapy and topical imiquimod are both effective in superficial BCC
- BCC in patients with Gorlin syndrome should not be treated with radiotherapy
- Hedgehog pathway inhibitors can induce clinical response in patients with advanced inoperable BCC

**Squamous cell carcinoma**

- Excision is the treatment of choice for invasive SCC
- Most recurrences or metastases occur within 5 years
- Medical management is not usually considered for invasive SCC

**Carcinoma in situ (Bowen’s disease)**

- For single/few lesions on good healing sites, cryotherapy, curettage, photodynamic therapy, topical imiquimod and 5-fluorouracil are options
- For multiple lesions and/or poor healing sites such as the lower leg, photodynamic therapy, where feasible, is the treatment of choice, although topical 5-fluorouracil or imiquimod are alternative treatments

**Actinic keratoses**

- For single/few lesions on good healing sites, cryotherapy, curettage and 5-fluorouracil + salicylic acid are options, especially if hyperkeratotic
- For multiple lesions/field change, topical 5-fluorouracil, conventional or daylight photodynamic therapy, imiquimod or diclofenac in hyaluronic acid gel may be effective

---

![Fig. 27.12 Basal cell carcinoma. A] A nodular BCC showing the translucent nature of the tumour and the abnormal arterising vessels. B) An ulcerated BCC showing the raised, rolled edge.](image-url)
photochemically activated by visible (normally red) light, usually delivered by a light-emitting diode (LED), in the presence of oxygen, causing the production of reactive oxygen species, which cause destruction of treated tissue. The photosensitiser is taken up preferentially by diseased skin, and adverse effects in normal skin are minimised. PDT is at least as effective as cryotherapy and surgery for superficial BCC and may be preferred at sites of poor healing, such as the lower leg, or where cosmetic outcome is important. PDT is not as effective as surgery for long-term clearance of nodular BCC but can be considered if surgery is not appropriate. Pain during irradiation may occur during PDT, although adjustments to the irradiation regime can reduce discomfort and treatment is usually well tolerated. PDT is typically undertaken in the outpatient clinic setting and is well suited to frail patients and those unable to undertake treatment with topical agents at home.

Rarely, advanced BCC may be locally invasive or even metastasise. Major advances have been made in targeted drug development, and Hedgehog pathway inhibitors, such as vismodegib and sonidegib, can be used effectively for disease control and palliation in this setting, although there may be significant associated drug-induced toxicity.

### Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignancy that arises from epidermal keratinocytes and is the second most common skin cancer, occurring most frequently in older adult males and smokers. There is a close association between cumulative UVR exposure and SCC risk, with most SCC lesions occurring on chronically sun-exposed sites in light-skinned populations and often arising at sites of field-change carcinogenesis, with coexistent precursors of AK and BD commonly evident. In the immunosuppressed patient population, such as organ transplant recipients, SCC is the most common skin cancer and its incidence is dramatically increased, particularly in association with the duration of immunosuppression and the degree of sun exposure and damage accrued pre-transplant. The risk of SCC is also increased in HIV infection. Furthermore, SCC arising in the immunosuppressed is more likely to behave aggressively or to metastasise.

### Clinical features

The tumours usually occur on chronically sun-exposed sites, such as bald scalp, tops of ears, face and back of hands. The clinical presentation may be diverse, ranging from rapid development of a painful keratotic nodule in a pre-existing area of dysplasia (Fig. 27.13) to the de novo presentation of an erythematous, infiltrated, often-warty nodule or plaque that may ulcerate. The clinical appearance depends on histological grading; well-differentiated tumours more often present as defined keratotic nodules (Fig. 27.13A), whereas poorly differentiated tumours tend to be ill defined and infiltrative, and may ulcerate. SCC has metastatic potential; some tumours, such as those on lips and ears and in immunosuppressed patients, behave more aggressively and are more likely to metastasise to draining lymph nodes.

### Management

Early diagnosis is important and complete surgical excision is the usual treatment of choice (see Box 27.15). Standard excision with a 4–6mm margin is advised and the cure rate is approximately 90%–95%. Mohs’ surgery is an option but is used less frequently for SCC than for BCC. High-risk SCC should be treated aggressively, with a wider margin of excision of at least 6mm where feasible. This may include larger, thicker lesions, tumours at sites where metastases are more likely, such as the ear, lip or non-sun-exposed sites, and those occurring in the immunosuppressed and/or with histology showing the tumour to be poorly differentiated, with evidence of lymphatic, vascular or perineural involvement or a high mitotic index. Such patients and those with metastatic disease require management via a multidisciplinary team. In patients who are at high risk for further SCC, systemic retinoids may have a role in reducing the rate of SCC development, but rapid appearance of tumours occurs on drug cessation. Occasionally, curettage and cautery may be appropriate if the tumour is small and low-risk and either surgical excision is contraindicated or the patient is unwilling to proceed with excision. Radiotherapy may be indicated if surgical excision is not feasible. Cryotherapy and topical non-surgical therapies are not usually used in invasive SCC because of risk of recurrence and metastasis.

### Actinic keratosis

Actinic keratoses (AK) are scaly, erythematous lesions arising on chronically sun-exposed sites. Histology shows dysplasia, although the diagnosis of typical AK is usually made on clinical grounds (Fig. 27.14). They are common in fair-skinned people who have had significant sun exposure, are often multiple and increase with age. The prevalence is much higher in Australia than in the UK and some surveys have shown a prevalence of more than 50% in those over 40 years old. The rate of progression to SCC is less than 0.1% and spontaneous resolution is possible. However, SCC can also arise de novo and without progression from AK. Increase in size, ulceration, bleeding, pain or tenderness can be indicative of transformation into SCC.

![Fig. 27.13 Squamous cell carcinoma. A A centrally keratinous, symmetrical, well-differentiated SCC. Clinically, this could be confused with keratoacanthoma. B An SCC arising from an area of epidermal dysplasia.](image)

![Fig. 27.14 Actinic keratosis. Close-up of a hyperkeratotic AK on the ear.](image)
**Management**

Several treatments are available for AK (see Box 27.15). Emollients and photoprotection, including high-factor sunscreens, may suffice for mild disease. Single or low numbers of lesions of AK can be effectively treated with cryotherapy. Hyperkeratotic lesions may be treated with the antimitabolite 5-fluorouracil, combined with salicylic acid, or may require curettage and cautery.

Multiple lesions require field-directed therapy; 5-fluorouracil is widely used in this setting as an effective initial therapeutic approach and topical imiquimod is an alternative. Diclofenac in a hyaluronic acid gel base can also be used topically for low-grade maintenance control of AK, the rationale for its use being the over-expression of cyclo-oxygenase (COX)-2 in AK lesions. PDT is widely used for field-change multiple AK, with high efficacy rates; it is at least as effective as cryotherapy or 5-fluorouracil. The relative selectivity of treatment allows subclinical disease to be treated, while sparing normal skin. A regimen using daylight to activate the photosensitiser is increasingly and widely used for extensive mild AK, with high efficacy rates, comparable to hospital-based PDT but without the need for specialised equipment and allowing patients to be treated at home.

**Bowen’s disease**

**Clinical features**

Bowen’s disease (BD) is the name given to an intra-epidermal carcinoma that usually presents as a slowly enlarging, erythematous, scaly plaque on the lower legs of fair-skinned older women (Fig. 27.15) but other sites can also be involved. It can be confused with eczema or psoriasis, but is usually asymptomatic and does not respond to topical glucocorticoids. It may also be hard to distinguish from superficial BCC. Transformation into SCC occurs in 5% or less.

**Diagnosis**

Incisional biopsy is usually undertaken to confirm the diagnosis. This shows an intra-epidermal carcinoma with no invasion through the basement membrane. Histology may also be obtained by curettage but this does not allow distinction from invasive SCC to be made, due to loss of tissue orientation and architecture.

**Management**

While curettage or excision may be appropriate in some settings, non-surgical therapies are generally preferred (see Box 27.15), especially on the lower legs. PDT, in particular, may be advantageous for BD on the lower leg because of relative selectivity of treatment and sparing of normal tissue, thus reducing the risk of poor healing and ulceration at this vulnerable site. Given the low risk of malignant transformation, the option of no active treatment may also be appropriate for some frail patients with multiple co-morbidities.

**Cutaneous lymphomas**

The most common form of cutaneous T-cell lymphoma is mycosis fungoides (MF). This can persist for years in patch and plaque stages, often resembling eczema or psoriasis. Only sometimes does it progress through to nodules and finally a systemic stage, Sézary syndrome. B-cell lymphomas, on the other hand, usually present as nodules or plaque-like tumours. The diagnosis of cutaneous T-cell lymphoma requires a high index of suspicion, particularly in patients thought to have unusual recurrent forms of eczema or psoriasis.

Treatment is symptomatic and there is no evidence that it alters prognosis. In the early stages of cutaneous T-cell lymphoma, systemic or local glucocorticoids may be indicated; alternatively, narrowband UVB phototherapy (for patch-stage MF) or PUVA (for plaque-stage MF) may be used. Once lesions have moved beyond plaque stage, localised radiotherapy, electron beam radiation, the synthetic retinoid bexarotene, interferon-alfa, extracorporeal photopheresis and systemic anti-lymphoma chemotherapy regimens may be needed. Management of advanced disease invariably requires a multidisciplinary team approach, with collaboration between dermatologists, pathologists and haematological oncologists.

**Melanoma**

Melanoma is a malignant tumour of epidermal melanocytes. While only 4% of skin cancers are melanomas, they account for 80% of skin cancer deaths. There has been a steady rise in the incidence of melanoma in fair-skinned populations over recent decades, with the highest incidence in Australasia. Primary prevention and early detection are essential, as therapy for advanced and metastatic disease, whilst being a rapidly evolving field, remains challenging and unsatisfactory.

**Pathophysiology**

Risk factors for melanoma include fair skin, freckles, red hair, number of naeves and sunlight exposure. The type of sunlight exposure is under debate but intermittent exposure, such as recreational time in the sun, sunburn and sunbed use, is implicated. Patients with multiple atypical naeves (dysplastic naevus syndrome) and fair-skinned people, often with variant alleles in the melanocortin-1 gene, are at increased risk of melanoma. A family history of melanoma increases the risk but a strong family history is unusual. Rarely, autosomal dominant inheritance of melanoma with incomplete penetrance can occur due to mutations in CDKN2A, which encodes the p16 tumour suppressor protein. In these patients, the lifetime risk of melanoma is more than 50%. Several other susceptibility genes and potential genetic targets for therapeutic intervention in advanced disease have also been identified.

**Clinical features**

Melanoma can occur at any age and site and in either sex, but typically affects the leg in females and back in males. It is rare before puberty. The classification of invasive malignant melanoma is shown in Box 27.16. Early lesions may be in situ and pre-invasive before becoming invasive melanoma with metastatic potential. Any change in naevus or development of new lesions should be assessed to exclude malignancy and, for this, the dermatoscope is invaluable (see Fig. 27.2). Real-time non-invasive imaging techniques are being investigated as tools to assist in diagnosis but are largely experimental. If there is any doubt, excision is advised.

**Superficial spreading melanoma**

Superficial spreading melanoma (SSM) is the most common type in light-skinned populations. It usually presents as a slowly enlarging, macular, pigmented lesion, with increasing irregularity in shape and pigment; this superficial, radial growth phase can last for approximately 2 years. Subsequently, the lesion may become palpable and this is indicative of a vertical growth phase, with dermal invasion; when this occurs, the tumour has the potential to invade lymphatics and vessels and to become metastatic (Fig. 27.16A). Approximately 50% of melanomas arise from a pre-existing naevus.

**Nodular melanoma**

Nodular melanoma is most common in the fifth and sixth decades, particularly in men and on the trunk (Fig. 27.16B). This may account in part...
of lymphovascular or perineural involvement should also be ascertained. The clinical staging of melanoma extent is essential, in order to establish whether disease is primary and localised, or if there is nodal or metastatic spread.

Wide excision of melanoma with a low risk of metastasis (stage 1 disease, Breslow thickness <1 mm) with a 1 cm clear margin is accepted practice. The margin of excision for more advanced disease is controversial, although a 2–3 cm margin for thicker tumours is generally advised as an attempt to reduce risk of local recurrence. There is no evidence that more radical surgery with 4–6 cm margins is beneficial. The majority of tumours can be excised without the need for grafting. For tumours with a Breslow thickness of 0.8–1 mm or more, a sentinel lymph node biopsy is indicated and should be considered on a case-by-case basis as, in addition to provision of prognostic information, a positive sentinel node biopsy facilitates access to adjuvant treatment with either targeted therapy and/or immune checkpoint inhibitors and is only required before entry to clinical trials of new treatments. Patients must be counselled about the sentinel node biopsy procedure, which is usually performed at the time of wider excision. It involves injection of radio-labelled blue dye at the site of the primary melanoma, allowing identification of the draining ‘sentinel’ node by radioisocintigraphy; this sentinel node is then removed and examined in detail by histology, immunohistochemistry and/or PCR of melanocyte gene products to look for tumour deposits.

If the biopsy is positive, adjuvant therapy should be considered as described below and has largely replaced the need for complete local lymphadenectomy, which is a procedure that is associated with high morbidity in terms of lymphoedema and has no proven survival benefit. Nowadays it is only undertaken if there is a high risk of bulky locoregional recurrence.

Localised cutaneous or nodal recurrence may be treated surgically and cutaneous metastases or in transit disease may be amenable to palliation with electrochemotherapy if there is no evidence of widespread metastatic disease.

There have been major advances in treatment options for advanced melanoma, such that patients are often now able to have extended survival, sometimes for many years. However, ultimately the overall prognosis for metastatic disease remains poor and treatment options remain palliative, with disease control as opposed to cure. Genetic developments have facilitated the introduction of tumour-targeted treatments for advanced, unresectable and/or metastatic disease, such as the B-Raf and c-Kit kinase inhibitors for patients expressing these gene mutations, notably dabrafenib and vemurafenib, with demonstrable clinical responses. Combined BRAF and MEK targeted inhibition, with drugs such as trametinib, may also be used. Immune checkpoint inhibition with ipilimumab, which causes T-cell activation by inhibiting CTLA-4, alone or in combination with the programmed cell death (PD1) pathway blockers nivolubum or pembrolizumab, provides clinically meaningful improvements in quality of life and survival to patients with advanced disease. Standard chemotherapy may also be used in some cases of metastatic disease, although outcomes are poor. Other biologic and gene therapies and vaccines are also being investigated. It is important for patients with advanced melanoma to be managed through a multidisciplinary team in order to optimise care, provide access to adjuvant therapy and facilitate their inclusion in clinical trials.

All patients should be advised regarding ongoing photoprotection, with sensible behaviour in the sun, covering up, wearing hats and high-factor sunscreen use. However, evidence has shown that despite patients with melanoma being advised to photoprotect, many follow this advice only for the first year following diagnosis, thus emphasising the need for ongoing reinforcement of guidance with regard to photoprotection. It is also prudent to advise patients who are photoprotecting to optimise oral vitamin D through diet and/or supplements.

**Prognosis**

Prognosis is influenced by several factors, including tumour characteristics and thickness (Breslow thickness) and the presence or absence of regional, nodal or metastatic disease. Patients with in situ melanoma do

**Diagnosis and management**

The diagnosis is made by excision biopsy of a suspicious lesion. The initial biopsy should include a 2 mm margin, followed up where possible by wider excision if the diagnosis is confirmed. Occasionally, radiotherapy or imiquimod may be used for lentigo maligna, if surgery is not feasible. The Breslow thickness of the tumour (the maximal depth from epidermal granular cell layer to deepest tumour cells) is critical for management and prognosis. The presence of ulceration may lead to under-estimation of the Breslow thickness and may also adversely affect prognosis. The mitotic rate and the presence or absence of any evidence

---

not have risk of metastasis and those with an invasive primary tumour of less than 1 mm Breslow thickness have more than a 90% chance of 5-year disease-free survival, but this figure drops to approximately 50% for a tumour of greater than 3.5 mm thickness. Survival rates fall to less than 10% for those with advanced nodal or metastatic disease.

**Benign skin lesions**

In practice, it is often difficult to distinguish between skin cancer and a benign lesion on clinical grounds; if there is any doubt, biopsy and histology are required. Benign melanocytic naevi and basal cell papilloma, in particular, can often be mistaken for melanoma, even by dermatologists. Keratoacanthoma, while benign, is also commonly considered to be invasive SCC on clinical grounds.

**Keratoacanthoma**

This benign tumour has a striking clinical presentation of rapid growth over weeks to months and subsequent spontaneous resolution. It is thought to be associated with chronic sun exposure and most commonly occurs on the central face. The classical appearance is of an isolated dome-shaped nodule often of 5 cm or more in diameter, with a central keratin plug (Fig. 27.17). Clinically and histologically, the lesion often resembles SCC (see Fig. 27.13A). Most are treated surgically, either by curettage and cautery or by excision, to rule out SCC and to avoid the unsightly scar after spontaneous resolution.

**Freckle**

Histologically, a freckle (ephelis) consists of normal numbers of melanocytes, but with focal increases in melanin in keratinocytes. They are most common on sun-exposed sites in fair-skinned individuals, particularly children and those with red hair, and on the face. There is a familial tendency. Clinically, freckles are brown macules that darken following UVR exposure.

**Lentigo**

A lentigo (plural lentigines) consists of increased numbers of melanocytes along the basement membrane, but without formation of the nests that occur in melanocytic naevi. These lesions usually occur at sites of chronic sun exposure (see the background skin changes in Fig. 27.13A), become more common with age, and are often referred to as ‘liver spots’ or ‘age spots’. They can vary in colour from light to very dark brown. Distinction from melanoma is essential and histology may be required.

**Haemangiomas**

Benign vascular tumours or hamartomas are common and include Campbell de Morgan spots (see Fig. 27.18), which present as pink/red papules on the upper half of the body. They can sometimes be difficult to distinguish from melanocytic lesions, particularly if they are thrombosed or occur on particular sites, such as the lip or genitalia. The dermatoscope is helpful for this (see Fig. 27.2).

**Basal cell papilloma**

Basal cell papillomas (also known as seborrhoeic warts or keratoses) are common, benign epidermal tumours (Fig. 27.18). They may be flat, raised, pedunculated or warty-surfaced, and can appear to be ‘stuck on’. They occur in both sexes and with increasing age, and are most common on the face and trunk. The colour may vary from yellow to almost black and the surface may seem ‘greasy’, with pinpoint keratin plugs visible, particularly with a magnifying lens. If there is no doubt about the diagnosis, they can be left alone or treated by cryotherapy or curettage if they are cosmetically troublesome. If there is a suspicion of melanoma, excision or diagnostic biopsy should be undertaken.

**Melanocytic naevi**

Melanocytic naevi (moles) are localised benign clonal proliferations of melanocytes. It is thought that they may arise as the result of abnormalities in the normal migration of melanocytes during development. It is quite normal to have 20–50, although, interestingly, individuals with red hair have fewer. Genetic and environmental factors are implicated. Monozygotic twins have higher concordance in naevi numbers than dizygotic twins. Individuals who have had greater sun exposure have higher numbers of naevi. Most melanocytic naevi appear in childhood and early adult life, or during pregnancy or oestrogen therapy. The onset of a new mole is less common after the age of 25 years. Congenital melanocytic naevi occur at or shortly after birth.

**Clinical features**

Acquired melanocytic naevi are classified according to the microscopic location of the melanocyte nests (Fig. 27.19). Junctional naevi are usually macular, circular or oval, and mid- to dark brown. Compound and intradermal naevi are nodules because of the dermal component, and may be hair-bearing. Intradermal naevi are usually less pigmented than compound naevi. Their surface may be smooth, cerebriform, hyperkeratotic or papillomatous.

Some individuals have large numbers of naevi, often at unusual sites, such as the scalp, palms or soles, and these may frequently appear ‘atypical’ in terms of variability in pigmentation, size and shape. Some may be very dark or pink and may show a depigmented or inflamed halo.

---

Fig. 27.17 Keratoacanthoma.

Fig. 27.18 A typical basal cell papilloma. Note the neighbouring basal cell papillomas and the coincidental benign angomas (Campbell de Morgan spots).
If these naevi are removed, then ‘dysplastic changes’ are often seen. Such naevi are known to occur in some rare families with an inherited melanoma predisposition. However, the significance of such changes in non-familial cases is unclear and there is no consensus on management and follow-up.

Although approximately 50% of melanomas arise in pre-existing naevi, most naevi do not become malignant; although a changing naevus must be taken seriously, most will not be melanomas. Malignant change is most likely in large congenital melanocytic naevi (risk may correlate with size of lesion) and possibly in families where there is a history of large numbers of atypical naevi and/or a history of melanoma.

**Diagnosis and management**

Melanocytic naevi are normal and do not require excision, unless malignancy is suspected or they become repeatedly inflamed or traumatised. Advice on photoprotection is important for fair-skinned individuals with multiple naevi.

## Blue naevi

These are melanocytic naevi in which there is a proliferation of spindled melanocytes relatively deep within the dermis. Light scattering means that the pigment appears blue rather than brown. They may be difficult to distinguish from nodular melanoma and are therefore often excised.

## Dermatofibroma

A dermatofibroma is a characteristically firm, often pigmented, raised lesion, most commonly found on the lower legs. Its aetiology is unclear, although a reactive process secondary to insect bites or trauma is one hypothesis. There is frequently a ring of pigment around the lesion and dimpling when the skin is pinched, reflecting epidermal tethering.

## Acrochordon

Acrochordons, or skin tags, are benign pedunculated lesions; they are most common in skin flexures and usually have a very characteristic clinical appearance. However, they may sometimes be confused with melanocytic naevi. Treatment is not required unless there is diagnostic doubt or they are causing symptoms, such as irritation, or for cosmetic reasons. Cryotherapy or snip or shave excision may be appropriate in that situation.

## Lipoma

Lipomas are benign tumours of adipocytes that are characteristically soft and lie more deeply in the skin than epidermal tumours; they are usually diagnosed easily on clinical grounds. A variant, angiolipoma, is typically painful. Treatment is not required unless there is diagnostic doubt or they are symptomatic or cosmetically troublesome, in which case a diagnostic biopsy or surgical excision may be required.

### Common skin infections and infestations

#### Bacterial infections

**Impetigo**

Impetigo is a common and highly contagious superficial bacterial skin infection. There are two main presentations: bullous impetigo, caused by a staphylococcal epidermolytic toxin, and non-bullous impetigo (Fig. 27.20), which can be caused by either *Staphylococcus aureus* or streptococci, or both together. *Staphylococcus* spp. are the most common agents in temperate climates, whereas streptococcal impetigo is more often seen in hot, humid areas. All ages can be affected but non-bullous disease particularly affects young children, often in late summer. Outbreaks can arise in conditions of overcrowding and poor hygiene or in institutions. A widespread form can occur in neonates. Predisposing factors are minor skin abrasions and the existence of other skin conditions, such as infestations or eczema.

In non-bullous impetigo, a thin-walled vesicle develops; it rapidly ruptures and is rarely seen intact. Dried exudate, forming golden crusting, arises on an erythematous base. In bullous disease, the toxins cleave desmoglein-1, causing a superficial epidermal split and the occurrence of intact blisters with clear to cloudy fluid, which last for 2–3 days. The face, scalp and limbs are commonly affected but other sites can also be involved, particularly if there are predisposing factors such as eczema. Lesions may be single or multiple and coalesce. Constitutional symptoms are uncommon. A bacterial swab should be taken from blister fluid or an active lesion before treatment commences. Around one-third of the population is a nasal carrier of *Staphylococcus*, so swabs from the nostrils should also be obtained.

In mild, localised disease, topical treatment with mupirocin or fusidic acid is usually effective and limits the spread of infection. The use of topical antiseptics and soap and water to remove infected crusts is also helpful. *Staphylococcal* carriage should be treated, with mupirocin topically to the nostrils, if swabs are positive. In severe cases, an oral antibiotic, such as flucloxacillin or clarithromycin, is indicated. If nephrotoxic streptococci are isolated then systemic antibiotics should be considered to reduce the risk of streptococcal glomerulonephritis. Underlying disease, such as infestations, must be treated and cross-infection minimised. Scarring does not occur but there may be temporary dyspigmentation.
toxins and early cases were thought to arise with tampon use. Intensive supportive care and systemic antibiotics are required.

**Ecthyma**

Ecthyma is caused by either staphylococci or streptococci, or both together, and is characterised by adherent crusts overlying ulceration. It occurs worldwide but is more common in the tropics. In Europe, it occurs more frequently in children. Predisposing factors include poor hygiene, malnutrition and underlying skin disease, such as scabies. It is commonly seen in drug abusers, and minor trauma can predispose to lesion development. Management approaches are similar to impetigo as ecthyma can be considered as a deeper version of impetigo. Crust removal, antiseptics and systemic antibiotics may be required.

**Folliculitis, furuncles and carbuncles**

Hair follicle inflammation can be superficial, involving just the ostium of the follicle (folliculitis), or deep (furuncles and carbuncles).

**Superficial folliculitis**

The primary lesions are follicular pustules and erythema. Superficial folliculitis is often infective, caused by *Staph. aureus*, but can also be sterile and caused by physical (for example, traumatic epilation) or chemical (for example, mineral oil) injury. Staphylococcal folliculitis is most common in children and often occurs on the scalp or limbs. Pustules usually resolve without scarring in 7–10 days but can become chronic. In older children and adults, they may progress to a deeper form of folliculitis. The condition is often self-limiting and may respond to imminent removal and antiseptics. More severe cases may require topical or systemic antibiotics and treatment of *Staph. aureus* carrier sites.

**Deep folliculitis (furuncles and carbuncles)**

A furuncle (boil) is an acute *Staph. aureus* infection of the hair follicle, usually with necrosis. It is most common in young adults and males. It is usually sporadic but epidemics occasionally occur. Malnutrition, diabetes and HIV predispose, although most cases arise in otherwise healthy people. All body sites can involve but neck, buttocks and anogenital areas are commonly affected areas. Infection is often associated with chronic *Staph. aureus* carriage in the nostrils and perineum, and may be due to resistant strains, such as methicillin-resistant organisms (MRSA). Friction caused by tight clothing may be contributory. Initially, an inflammatory follicular nodule develops and becomes purulent, fluctuant and tender. Crops of lesions sometimes occur. There may be fever and mild constitutional upset. Lesions rupture over days to weeks, discharge pus, become necrotic and leave a scar.

If a deep *Staph. aureus* infection of a group of contiguous hair follicles occurs, this is termed a carbuncle and is associated with intense deep inflammation (Fig. 27.22). This usually occurs in middle-aged men, often

**Staphylococcal scalded skin syndrome**

Staphylococcal scalded skin syndrome (SSSS) is a potentially serious exfoliating condition occurring predominantly in children, particularly neonates (Fig. 27.21). It is caused by systemic circulation of epidermolytic toxins from a *Staph. aureus* infection. The same toxins are implicated in bullous impetigo, which is a localised form of SSSS. The focus of infection may be minor skin trauma, the umbilicus, urinary tract or nasopharynx. The child presents with fever, irritability and skin tenderness. Erythema usually begins in the groin and axillae, and around the mouth. Blisters and superficial erosions develop over 1–2 days and can rapidly involve large areas, with severe systemic upset. Bacterial swabs should be obtained from possible primary sites of infection. A skin snip should also be taken for urgent histology. This is a sample of the superficial peeling skin removed by ‘snipping with scissors’, without the need for local anaesthetic. It shows a split beneath the stratum corneum, and differentiates SSSS from toxic epidermal necrolysis, in which the whole epidermis is affected (see Fig. 27.41). Systemic antibiotics and intensive supportive measures should be commenced immediately. Bacterial swabs from nostrils, axillae and groins should be taken from family members to exclude staphylococcal carriage. Although the acute presentation of SSSS is often severe, rapid recovery and absence of scarring are usual, as the epidermal split is superficial.

**Toxic shock syndrome**

This condition is characterised by fever, desquamating rash, circulatory collapse and multi-organ involvement. It is caused by staphylococcal
with predisposing conditions such as diabetes or immunosuppression. A carbuncle is an exquisitely tender nodule, usually on the neck, shoulders or hips, associated with severe constitutional symptoms. Discharge, necrosis and scarring are usual. Bacterial swabs must be taken and treatment is with anti-staphylococcal antibiotics, e.g. flucloxacillin, and sometimes incision and drainage.

Other staphylococcal toxins may also be pathogenic. For example, Panton–Valentine Leukocidin (PVL)-producing Staph. aureus can cause recurrent abscesses (definition: localised collections of pus in cavities) and may be difficult to eradicate.

**Cellulitis and erysipelas**

Cellulitis is inflammation of subcutaneous tissue, due to bacterial infection (Fig. 27.23). In contrast, erysipelas is bacterial infection of the dermis and upper subcutaneous tissue (Fig. 27.24), although in practice it may be difficult to distinguish between them. These conditions are most commonly caused by group A streptococci but culture of swabs from affected sites is often negative. There is frequently a source of organism entry, such as an ear infection, varicose eczema/ulcer or tinea pedis, and swabs should also be taken from these sites. Diabetes and immunosuppression are predisposing factors. The patient usually has malaise, fever and leucocytosis, and streptococcal serology will often be positive. The face (erysipelas) and legs (cellulitis) are most often affected and the site is hot, painful, erythematous and oedematous. Blistering often occurs and may be haemorrhagic. Regional lymphadenopathy is common. Erysipelas typically has a well-defined edge due to its more superficial level of involvement, whereas cellulitis is typically ill defined. Treatment is usually with intravenous flucloxacillin, with clarithromycin, clindamycin and vancomycin as alternatives for penicillin-allergic patients. Milder cases may be treated with oral antibiotics. If cases are untreated, seque-}

**Mycobacterial infections**

*Mycobacterium leprae* infection may involve the skin and its manifestations will be influenced by host immunity, patients with high levels of immunity presenting with paucibacillary tuberculous leprosy and those with low immune resistance developing multibacillary lepromatous leprosy. Hypopigmented or erythematous patches, with associated altered or lost sensation, or skin thickening, nodules and infiltration should raise suspicion of a diagnosis of leprosy. The skin may also be an extrapulmonary site of involvement in tuberculosis, usually due to infection with *Mycobacterium tuberculosis*. Skin manifestations depend on the route of infection, previous sensitisation and host immunity. There may be a variety of cutaneous features, including the red–brown scarring inflammatory plaques seen in lupus vulgaris due to direct skin inoculation; scrofuloderma, which describes the skin changes overlying lymph nodes or joints infected with tuberculosis; and the reactive nodular and ulcerated changes seen in patients with high levels of immune response, notably the tuberculoids and erythema induratum (Bazin's disease). On disinsection, an 'apple jelly' appearance is typically seen, indicating the granulomatous nature of skin involvement. Granulomas evident on skin biopsy should certainly raise suspicion of a diagnosis of mycobacterial infection. Culture of organisms may be tricky but PCR can assist with diagnosis. Patients should be thoroughly investigated for signs of tuberculosis at pulmonary or other extrapulmonary sites. Reactivation of latent tuberculosis is a particular concern for patients receiving treatment with immunosuppressants and biologic agents, particularly TNF-α antagonists for conditions such as psoriasis. Vigilance is required in screening and workup of such patients prior to consideration of these therapeutic agents. Management of tuberculosis is discussed in Chapter 17.

Other mycobacterial skin infections may occur, such as *Mycobacterium marinum*, typically seen in those who clean tropical fish tanks. Sporotrichoid spread of granulomatous nodules from the site of inoculation along lymphatics is typical; granulomatous changes are seen on histology and resolution usually occurs with a prolonged course of antibiotics such as doxycycline or minocycline. Resolution may also take place spontaneously or after destructive therapies, such as cryotherapy.

**Leishmaniasis**

This protozoan infection may be restricted to the skin or there may be systemic features depending on the species, which occur in different geographical areas. The clinical features and management of this condition are discussed in Chapter 13.

**Necrotising soft tissue infections and anthrax**

These conditions are discussed in more detail in Chapter 13.

**Erythrasma**

Erythrasma is a mild, chronic, localised, superficial skin infection caused by Corynebacterium minutissimum, which is part of the normal skin flora. Warmth and humidity predispose to this infection, which usually occurs in flexures and toe clefts. It is asymptomatic or mildly itchy and lesions are well defined, red–brown and scaly. C. minutissimum has characteristic coral-pink fluorescence under Wood's light. Microscopy and culture of skin scrapings can confirm the diagnosis but are not usually needed if Wood's light examination is positive. A topical azole (clotrimazole or miconazole) or fusidic acid is usually effective. Oral erythromycin can be used for extensive or resistant disease. Antiseptics can be used to prevent disease recurrence.
Pitted keratolysis

This is another superficial skin infection caused by *Corynebacterium* and *Streptomyces* spp., and possibly other organisms, producing characteristic circular erosions (“pits”) on the soles. It is usually asymptomatic. The bacterium can be identified in skin scrapings and typically occurs in association with hyperhidrosis, which must be treated to prevent recurrence. Treatment is as for erythrasma.

Other bacterial skin infections

Syphilis and the non-venereal treponematoses are discussed in Chapter 15. There has been a marked increase in incidence of syphilis. Skin signs may be subtle; for example, secondary syphilis may be misdiagnosed as pityriasis rosea. Lesions on palms, soles and mucosae should raise suspicion. Microscopic identification of the spirochaete may be possible and syphilitic serology should be undertaken using enzyme immunoassay or PCR-based techniques, depending on availability. Lyme disease can also cause a skin rash; the clinical features and management are described in Chapter 13.

Viral infections

Herpesvirus infections

The cutaneous manifestations of the human herpesviruses are described in more detail in Chapter 13. Topical antivirals may suffice for prophylaxis or treatment of mild viral disease, such as herpes simplex cold sore virus infection. Systemic antivirals are indicated for significant viral skin disease. For example, systemic aciclovir should be prescribed for eczema herpeticum (see Fig. 13.15C).

Papillomaviruses and viral warts

Viral warts are extremely common and are caused by the DNA human papillomavirus (HPV). There are over 90 subtypes, based on DNA sequence analysis, causing different clinical presentations. Transmission is by direct virus contact, in living or shed skin, and is encouraged by trauma and moisture, such as in swimming pools. Genital warts are spread by sexual activity and show a clear relationship with cervical and intra-epithelial cancers of the genital area. HPV-16 and 18 appear to inactivate tumour suppressor gene pathways and lead to squamous cell carcinoma of the cervix or intra-epithelial carcinoma of the genital skin. Vaccinations are available against HPV-16 and 18 and are recommended for females and males aged 12–13 years, before they become sexually active, with the objective of offering protective effects against cervical, genital, anal and some head and neck malignancies. The relationship between skin HPV and skin cancer is unclear. Individuals who are systematically immunosuppressed – after organ transplantation, for example – have greatly increased risks of skin cancer and HPV infection but a causal link is not certain.

Clinical features

Common warts are initially smooth, skin-coloured papules, which become hyperkeratotic and ‘warty’. They are most common on the hands (Fig. 27.25) but can occur on the face, genitalia and limbs, and are often multiple. Plantar warts (verrucae) have a slightly protruding rough surface and horny rim, and are often painful on walking. Paring reveals capillary loops that distinguish plantar warts from corns. Other varieties of wart include:

- mosaic warts: mosaic-like sheets of warts
- plane warts: smooth, flat-topped papules, usually on the face and backs of hands, which may be pigmented and therefore misdiagnosed
- facial warts: often filiform
- genital warts: may be papillomatous and exuberant.

Management

Most viral warts resolve spontaneously, although this may take years and active treatment is therefore often sought. However, asymptomatic warts generally should not be treated. Viral warts are particularly problematic and more recalcitrant to treatment in immunosuppressed patients following organ transplantation.

Treatments are destructive. Salicylic acid or salicylic/lactic acid combinations and regular wart paring for several months are the most consistently effective treatments. For certain types of warts, such as filiform facial warts, cryotherapy is generally the treatment of choice, but for common hand and foot warts salicylic acid wart paint should be used first. Cryotherapy is usually the next step and is repeated 2–4-weekly. However, caution is required, particularly on the hands, as over-vigorous cryotherapy can lead to scarring, nail dystrophy and even tendon rupture. Periungual and subungual warts can be problematic and nail cutting and subsequent electrodessication may help. Several other therapies have been used for recalcitrant warts, including topical formaldehyde, glutaraldehyde, podophyllotoxin, trichloroacetic acid, cantharidin, topical or systemic retinoids, intralesional bleomycin or interferon injections, and contact sensitisation with, for example, diphenycyprone. Imiquimod and PDT may also be beneficial, particularly for multiple warts in immunosuppressed patients, and laser therapy can have a role in some cases.

Molluscum contagiosum

Molluscum contagiosum is caused by a DNA poxvirus skin infection. It is most common in children over the age of 1 year, particularly those with atopic dermatitis. It also occurs frequently in immunosuppressed patients, including those with HIV. Lesions are dome-shaped, “umbilicated”, skin-coloured papules with central punctum (Fig. 27.26). They

![Fig. 27.25](image_url) Viral wart on the finger. The capillary loops are evident within the warty hyperkeratosis. Periungual sites are common and more difficult to treat.

![Fig. 27.26](image_url) Molluscum contagiosum. Some of the pearly lesions show characteristic umbilication. From Lissauer T, Carroll W. Illustrated textbook of paediatrics, 6th edn. Elsevier; 2022.
are often multiple and found at sites of apposition, such as the side of the chest and the inner arm. Spontaneous resolution occurs but can take months. Prior to resolution, they often become inflamed and may leave small, atrophic scars. Destructive therapies may be painful and risk scarring, and the decision not to treat is often sensible. Gentle squeezing with forceps after bathing can hasten resolution. If active treatment is needed, topical salicylic acid, potassium hydroxide, podophyllin, cantharidin, trichloracetic acid, imiquimod, cryotherapy, diathermy, curettage or laser treatment are therapeutic approaches that can be considered.

Orf

Orf is a parapoxvirus skin infection and is an occupational risk for those who work with sheep and goats. Inoculation of virus, usually into finger skin, causes significant inflammation and necrosis, which typically resolves within 2–6 weeks. No specific treatment is required, unless there is secondary infection. Erythema multiforme can be provoked by orf.

Other viral exanthems

Skin rash can be a feature of various other virus infections and these are discussed in more detail in Chapter 13.

Fungal infections

Fungal skin infections can be superficial (dermatophytes and yeasts) or, less commonly, deep (chromomycosis or sporotrichiosis); the latter are seen more often in tropical climates or in the immunocompromised. Dermatophyte infections (ringworm) are extremely common and usually caused by fungi of the Microsporum, Trichophyton and Epidermophyton species. The fungi can originate from soil (geophilic) or animals (zoophilic), or be confined to human skin (anthrophilic). Dermatophyte infections usually present with skin (tinea corporis), scalp (tinea capitis), groin (tinea cruris), foot (tinea pedis) and/or nail (onychomycosis) involvement (Fig. 27.27).

**Diagnosis**

Skin scrapings, hair pluckings or nail clippings must be taken from areas of disease activity – typically, the advancing lesion edge for skin involvement; the crumbling dystrophic nail and subungal hyperkeratosis for nail involvement, and plucked hair from scalp or other affected hair-bearing sites – in order to confirm the diagnosis by microscopy and culture.

**Management**

The azoles (ketoconazole, miconazole), triazoles (itraconazole, fluconazole) and triazoleamines (terbinafine) are used most widely in fungal skin disease. Topical antifungals such as terbinafine or miconazole may suffice, although systemic treatment (terbinafine, itraconazole or griseofulvin) may be required for stubborn or extensive disease and scalp or nail involvement. Indeed, prolonged courses of systemic treatment may be needed for nail involvement. The fungistatic agent griseofulvin, given orally, is usually used for fungal infection of scalp or nails in children in the UK, as it is the only drug licensed in children for this indication; outside the UK, and in adults, terbinafine is usually the treatment of choice as it has broader range of activity and shorter treatment duration. Itraconazole is also an effective alternative. In addition to systemic antifungals, short courses of systemic or topical glucocorticoid are often used in kerion on the basis of reducing inflammation and possible hair loss. However, glucocorticoid use is controversial, with no good evidence of benefit.

Tinea corporis

Tinea corporis should feature in the differential diagnosis of a red, scaly rash. Typically, lesions are erythematous, annular and scaly, with a well-defined edge and central clearing. There may also be pustules at the active edge. Lesions are usually asymmetrical and may be single or multiple. The degree of inflammation is dependent on the organism involved and the host immune response. Microsporum canis (from dogs) and T. verrucosum (from cats) are common culprits. Ill-advised use of topical glucocorticoids can modify the clinical presentation and increase disease extension (tinea incognito).

Tinea cruris

This is extremely common worldwide and is usually caused by *T. rubrum*. Itchy, erythematous plaques develop in the groins and extend on to the thighs, with a raised active edge (see Fig. 27.27A).

Tinea pedis

Tinea pedis or ‘athlete’s foot’ is the most common fungal infection in the UK and USA, and is usually caused by anthropophilic fungi, such as *T. rubrum*, *T. interdigitale* and *E. floccosum*. It typically presents as an itchy rash between the toes, with peeling, fissuring and maceration. Involvement of one sole or palm (tinea manuum) with fine scaling is characteristic of *T. rubrum* infection. Vesication or blistering is more often seen with *T. mentagrophytes*.

Tinea capitis

This is a dermatophyte infection of scalp hair shafts and is most common in children. It typically presents as an area of scalp inflammation and scaling, often with pustules and partial hair loss (Fig. 27.27B). Infection may be within the shaft (endothrix, most commonly caused by *T. tonsurans*), causing patchy hair loss with broken hairs at the surface (‘black dot’), little inflammation and no fluorescence with Wood’s light. Infection
outside the hair shaft (ectothrix, most commonly caused by *M. audouini* (anthropophilic)) shows minimal inflammation; *M. canis* (from dogs and cats) infections are more inflammatory and can be identified by green fluorescence with Wood’s light. Kerion is a boggy, inflammatory area of tinea capitis, usually caused by zoophilic fungi such as cattle ringworm (*T. verrucosum*).

### Onychomycosis

This is a fungal infection of the nail plate and the species involved are generally those that cause tinea capitis or tinea pedis. Onychomycosis usually presents with yellow/brown nail discoloration, crumbling, thickening and subungual hyperkeratosis. Usually, some nails are spared, there is asymmetry and toenails are more commonly involved.

### Candidiasis

This is a superficial skin or mucosal infection caused by a yeast-like fungus, *Candida albicans*. Infections are usually not serious, unless the patient is immunocompromised, in which case deeper tissues can be involved. The organism has a predilection for warm, moist environments and typical presentations are napkin candidiasis in babies, genital and perineal candidiasis, intertrigo and oral candidiasis. The diagnosis can be confirmed by microscopy and culture of skin swabs, and treatment is with topical or systemic antifungals, such as azoles.

### Pityriasis versicolor

Pityriasis versicolor is a persistent, superficial skin condition caused by various species of the commensal yeast *Malassezia*, most commonly *Malassezia globosa*, but sometimes *M. sympodialis* or *M. furfur*. It occurs in men and women and in different races. It is found more frequently in warmer, humid climates, and is usually more severe and persistent in the immunocompromised. It is characterised by scaly, oval macules on the upper trunk, usually hypopigmented but occasionally hyperpigmented. Hypopigmentation is more obvious after sun exposure and tanning. The diagnosis can be confirmed by microscopy of skin scrapings, showing ‘spaghetti and meatballs’ hyphae. Treatment with selenium sulphide or ketoconazole shampoos and topical or systemic azole antifungal agents is usually effective, although recurrence is common because these yeasts are commensals, and maintenance topical therapy may be required. Alteration of pigmentation can persist for months after treatment.

### Infestations

#### Scabies

Scabies is caused by the mite *Sarcoptes scabiei*. It spreads in households and environments where there is intimate personal contact. The diagnosis is made by identifying the scabetic burrow (definition: a linear or curvilinear papule, caused by a burrowing scabies mite — Fig. 27.29) and visualising the mite (by extracting with a needle or using a dermato-scope). In small children, the palms and soles can be involved, with pustules. Pruritus is prominent. The clinical features include secondary eczematization elsewhere on the body; the face and scalp are rarely affected, except in infants. Involvement of the genitals in males and of the nipples commonly occurs. Even after successful treatment, itch can continue and occasionally nodular lesions persist.

Topical treatment of the affected individual and all asymptomatic family members/physical contacts is required to ensure eradication. Two applications 1 week apart of an aqueous solution of permethrin or malathion to the whole body, excluding the head, are usually successful. If there is poor adherence, immunosuppression or heavy infestation (crusted ‘Norwegian’ scabies), systemic treatment with a single oral dose of ivermectin is sometimes appropriate.

![Fig. 27.28 Scabies. A] Scabies in a young child affecting the palm. B A mite still in its egg, seen on light microscopy of scrapings over a burrow. Note that the mite has only six legs, unlike adult mites, which have eight. (A) From Tissauer T, Carroll W. Illustrated textbook of paediatrics, 5th edn. Elsevier; 2018.](image)

#### Head lice

Infestation with the head louse, *Pediculus humanus capitis*, is common. It is highly contagious and spread by direct head-to-head contact. Scalp itch leads to scratching, secondary infection and cervical lymphadenopathy. The diagnosis is confirmed by identifying the living louse or nymph on the scalp or on a black sheet of paper after careful fine-toothed combing of wet hair following conditioner application. The empty egg cases (‘nits’) are easily seen on the hair shaft and are hard to dislodge.

Treatment is recommended for the affected individual and any infected household/school contacts. Eradication in school populations is difficult because of poor adherence and treatment resistance. Topical treatment with dimethicone, permethrin, carbaryl or, less often, malathion in lotion or aqueous formulations may be effective and should be applied twice at an interval of 7–10 days. Rotation treatments within a community may avoid resistance. “Wet-combing” (physical removal of live lice by regular combing of conditioned wet hair — ‘bug busting’) can suffice but may be less effective than pharmaco-tological treatments. Vaseline should be applied to eyelashes/brows twice daily for at least a fortnight. High-temperature washing of clothing and bedding is required. Treatment resistance and recurrence can be problematic.

#### Body lice

These are similar to head lice but live on clothing, particularly in seams, and feed on the skin. Poor hygiene and overcrowded conditions predispose. Itch, excoriation (definition: a linear ulcer or erosion resulting from scratching) and secondary infection occur. Dry-cleaning and high-temperature washing or insecticide treatment of clothes are required. Treatment options are as for head lice. For heavy infestation, oral ivermectin may be indicated.

#### Pubic (crab) lice

Usually, these are sexually acquired and very itchy. Management is as for head and body lice and whole-body treatment should be undertaken. Pubic hair may need to be shaved. Sexual and other close contacts
should also be treated and patients should also be screened for sexually transmitted diseases.

**Acne and rosacea**

**Acne vulgaris**

Acne is chronic inflammation of the pilosebaceous units. It is extremely common, generally starts during puberty and has been estimated to affect over 90% of adolescents. It is usually most severe in later adolescence but can persist into the thirties and forties, particularly in females (Box 27.17).

**Pathogenesis**

The key components are increased sebum production; colonisation of pilosebaceous ducts by *Propionibacterium acnes*, which in turn causes inflammation; and hypercornification and occlusion of pilosebaceous ducts (Fig. 27.29). Severity of acne is associated with sebum excretion rate, which increases at puberty. Both androgens and progesterogens increase sebum excretion and oestrogens reduce it, but most patients with acne have normal hormone profiles. There may be a positive family history and there is high concordance in monozygotic twins, indicating that genetic factors are important, but the candidate genes are poorly defined.

**Clinical features**

Acne usually affects the face and often the trunk. Greasiness of the skin may be obvious (seborrhoea). The hallmark is the comedone (definition: open comedones (blackheads) are dilated keratin-filled follicles, which appear as black papules due to the keratin debris; closed comedones (whiteheads) usually have no visible follicular opening and are caused by accumulation of sebum and keratin deeper in the pilosebaceous ducts – see Fig. 27.29). Inflammatory papules, nodules and cysts occur and may arise from comedones (Fig. 27.30). Scarring may follow deep-seated or superficial acne and may be keloidal. There are also distinct clinical variants:

- **Acne conglobata**: characterised by comedones, nodules, abscesses, sinuses (definition: cavities or channels that permit the escape of pus or fluid) and cysts, usually with marked scarring. It is rare, usually affecting adult males, and most commonly occurs on trunk and upper limbs. It may be associated with hidradenitis suppurativa (acne inversa) (an occlusive follicular chronic inflammatory condition affecting apocrine glands; this predominantly affects axillae, groins, perineal and perianal sites and follows a relapsing and remitting course and often requires complex medical and surgical management approaches), scalp folliculitis and pilonidal sinus.
- **Acne fulminans**: a rare but severe presentation of acne, associated with fever, arthralgias and systemic inflammation, with raised neutrophil count and plasma viscosity. It is usually found on the trunk in adolescent males. Costochondritis can occur.
- **Acne excoriée**: self-inflicted excoriations due to compulsive picking of pre-existing or imagined acne lesions. It usually affects adolescent girls, and underlying psychological problems are common.
- **Secondary acne**: comedonal acne can be caused by greasy cosmetics or occupational exposure to oils, tars or chlorinated aromatic hydrocarbons. Predominantly pustular acne can occur in patients using systemic or topical glucocorticoids, oral contraceptives, anticonvulsants, lithium or antineoplastic drugs, such as the epidermal growth factor receptor (EGFR) inhibitors. Most patients with acne do not have an underlying endocrine disorder but acne is a common feature of polycystic ovary syndrome which should be suspected if acne is moderate to severe and associated with hirsutism and menstrual irregularities. Vulvalisation should also raise suspicion of an androgen-secreting tumour.

![Fig. 27.29 Pathogenesis of acne.](image-url)

![Fig. 27.30 Cystic acne in an adolescent girl. A) Before treatment. B) After prolonged systemic antibiotic treatment.](image-url)
**Investigations**

Investigations are not required in typical acne vulgaris. Secondary causes and suspected underlying endocrine disease or virilisation should be investigated.

**Management**

**Mild to moderate disease**

Mild disease is usually managed with topical therapy. If comedones predominate, then topical benzoyl peroxide or retinoids should be used. Benzoyl peroxide has both anti-comedogenic and anti-inflammatory action. Topical retinoids, in particular all-trans retinoic acid and adapalene, are widely employed for mild to moderate comedonal acne vulgaris. Treatment should be initially applied at low concentrations for short duration and increased as tolerated. Patients with mild inflammatory acne should respond to topical antibiotics, such as erythromycin or clindamycin, which can be used in combination with other treatments.

For moderate inflammatory acne, a systemic tetracycline should be used at adequate dose for 3–6 months in the first instance (Fig. 27.30B). Oxytetracycline must be taken on an empty stomach, in a dose of up to 1.5 g a day. It has a good safety profile, even with long-term use, but adherence may be a challenge. Lymecycline is an alternative and is taken once daily, with or without food, thereby improving adherence. Doxycycline is another option but commonly causes photosensitivity. Minocycline is used less frequently, as it can cause hyperpigmentation, autoimmune hepatitis and drug-induced lupus, and monitoring is required. If the patient fails to respond, then alternatives include erythromycin or trimethoprim.

In women with acne, oestrogen-containing oral contraceptives can be a useful adjunct, as they are associated with a small reduction in sebum production. Combined oestrogen and anti-androgen (such as cyproterone acetate) contraceptives may provide additional efficacy, particularly in women with acne and hirsutism, as seen in polycystic ovary syndrome.

Patients should be referred for consideration of isotretinoin (13-cis-retinoic acid) if there is a failure to respond adequately to 6 months of therapy with these combined systemic and topical approaches.

**Moderate to severe disease**

Isotretinoin (13-cis-retinoic acid) has revolutionised the treatment of moderate to severe acne that has not responded adequately to other therapies. It has multifactorial mechanisms of action, with reduction in sebum excretion by over 90%, follicular hyperconflation, P. acne colonisation and inflammation. Oral isotretinoin is usually used at a dose of 0.5–1 mg/kg over 4 months. Sebum excretion typically returns to baseline within a year after treatment cessation, although clinical benefit is usually longer-lasting. Many patients will not require further treatment, although a second or third course of isotretinoin may be needed. A low-dose continuous or intermittent-dose regimen may occasionally be considered for a longer duration in patients who relapse after a higher-dose regimen, and may also be beneficial for older females with persistent acne. Combination with systemic glucocorticoids may be required in the short term for severe acne, in order to minimise the risk of disease flare early in the treatment course. Thorough screening and monitoring are required, given the side-effect profile of isotretinoin, particularly with respect to teratogenicity and possible mood disturbance. Pregnancy must be avoided during treatment and for a minimum of 2 months after drug cessation, and a strict pregnancy prevention programme and regular pregnancy testing are required. Depression and suicide have been reported in association with isotretinoin, although a causal role has not been established. However, pre-drug screening for depressive symptoms should be undertaken and mood monitored during therapy.

**Other treatments and physical measures**

Intralesional injections of triamcinolone acetonide may be required for inflamed acne nodules or cysts, which can also be incised and drained, or excised under local anaesthetic. Scarring may be prevented by adequate treatment of active acne. Keloid scars may respond to intralesional glucocorticoid and/or silicone dressings. Carbon dioxide laser, microdermabrasion, chemical peeling or localised excision can also be considered for scarring. UVB phototherapy or PDT can occasionally be used in patients with inflammatory acne who are unable to use conventional therapy, such as isotretinoin. There is no convincing evidence to support a causal association between diet and acne. The psychological impact of acne must not be under-estimated and should be considered in management decisions (see Box 27.17).

**Rosacea**

This chronic inflammatory condition affects the central face and consists of flushing, erythema, papules, pustules and telangiectasiae. The cause is unknown. Rosacea is distinct from acne vulgaris; sebum excretion is normal and comedones are absent. The relative contribution of Demodex mite and cutaneous vasomotor instability to the pathogenesis of rosacea remains poorly defined.

**Clinical features**

Rosacea most commonly affects fair-skinned, middle-aged females and can be exacerbated by heat, sunlight and alcohol. The convexities of nose, forehead, cheeks and chin are typically involved (Fig. 27.31). The condition is heterogeneous and intermittent flushing, followed by fixed erythema and telangiectasiae, predominates in some; in others, papules and pustules are prominent. Sebaceous gland hyperplasia and soft tissue overgrowth of the nose (rhinophyma) can occur, particularly in males. Conjunctivitis and blepharitis may also occur. Facial lymphoedema can be an added complication.

**Investigations**

Usually, no investigations are required and the diagnosis is obvious clinically. However, rosacea must be distinguished from acne vulgaris, systemic lupus erythematosus, photosensitivity disorders and seborrhoeic dermatitis (the latter may coexist with rosacea).

**Management**

Mild disease may respond to topical antimicrobials, such as metronidazole or azelaic acid. Topical ivermectin may be beneficial in some cases, supporting a contributory role of Demodex in pathogenesis. Tetracycline or erythromycin for 3–6 months is usually effective in inflammatory

---

pustular disease resistant to topical therapy. Relapse may require intermittent or chronic antibiotic use. Erythema and telangiectasias do not usually respond well to antibiotics but vascular laser therapy may be effective. Topical vasoconstrictors, such as the α₁-adrenoceptor agonist brimonidine, may be of benefit in some cases where erythema and telangiectasiae predominate. Systemic isotretinoin may be helpful in severe resistant disease and rhinophyma may require laser therapy or surgery.

### Eczemas

The term ‘eczema’ derives from the Greek word “to boil” and is synonymous with the other descriptive term, ‘dermatitis’. Eczema describes a clinical and histological pattern, which can be acute or chronic and has several causes. Acutely, epidermal oedema (spongiosis) and intra-epidermal vesication (producing multilocular blisters) predominate, whereas with chronicity there is more epidermal thickening (acanthosis). Vasodilatation and T-cell lymphocytic infiltration of the upper dermis also occur.

### Clinical features

There are several patterns of eczema (Box 27.18) but the clinical features are similar, irrespective of the cause (Box 27.19). Some subtypes of eczema have specific distinguishing features and these are discussed in more detail below.

### Investigations

Bacterial and viral swabs for microscopy and culture are important in suspected secondary infection. Bacterial swabs are commonly positive, particularly for staphylococci, although clinical assessment is required in order to ascertain whether swab results are of clinical significance and whether antibiotic treatment is required. Individuals with atopic eczema have an increased susceptibility to herpes simplex virus (HSV) and are at risk of developing a widespread infection, eczema herpeticum. The presence of small, punched-out lesions on a background of worsening eczema suggests the possibility of secondary HSV infection. Skin scrapings to rule out secondary fungal infection should also be considered. Total IgE and specific IgE tests and skin prick tests are not routinely undertaken in atopic eczema as they are not usually helpful, although they may occasionally be indicated in some cases as directed by the history. Patch tests should be performed if contact allergic dermatitis is suspected (see Box 27.23 below). Skin biopsy is not usually required unless there is diagnostic doubt.

### Classification of eczema

**Endogenous**
- Atopic, seborrhoeic

**Exogenous**
- Irritant, allergic, photo-allergic, chronic actinic dermatitis

### Characteristic patterns and morphology

- Asteatotic, discoid, gravitational, lichen simplex, pompholyx

### The clinical morphology of eczema

**Acute**
- Erythema, oedema, usually typically ill defined
- Papules, vesicles and occasionally bullae
- Exudation, tissuring
- Scaling

**Chronic**
- May be as above but less oedema, vesication and exudate
- Lichenification: skin thickening with pronounced skin markings, secondary to chronic rubbing and scratching
- Fissures (definition: slit-shaped deep ulcers), excoriations
- Dyspigmentation: hyper- and hypopigmentation can occur

### Management

A general approach to the management of eczema includes advice, education and support, required for patients with eczema of any type (Fig. 27.32). Input from patient support groups, such as the National Eczema Society in the UK, can be very helpful. Intensive and prolonged treatments are often required and chronic eczema can have a major and devastating adverse impact on personal and family lives. Emollients and topical glucocorticoids are mainstays of treatment for all eczema types, in order to improve skin barrier function, limit transepidermal water loss and reduce inflammation. Emollients can be used as bath additives and soap substitutes, and applied directly to the skin, often combined with antiseptics. Sedative antihistamines are useful if sleep is interrupted but non-sedating antihistamines are ineffective, as the itch of eczema is not primarily mediated by histamine.

Ointments are preferred for chronic eczema, whereas cream- or lotion-based treatment may be more appropriate for acute eczema (see Box 27.11). Treatment is once to twice daily. Hydrocortisone (1%) or clobetasone butyrate is generally used on the face, with more potent glucocorticoids restricted to trunk and limbs (see Box 27.12). A good strategy is to employ an intensive regimen with more potent glucocorticoids initially and then taper use according to response. A key principle is to use the least potent glucocorticoid that is effective for the shortest possible time. The patient should be given instructions on how much to apply, using the fingertip unit for guidance (a strip of glucocorticoid cream on distal phalanx pulp should cover two palm-size areas). It is also important to monitor glucocorticoid use and the easiest way to do this is ask the patient how long it takes them to use a specific size of glucocorticoid tube. The side-effects of topical glucocorticoid therapy need to be considered but glucocorticoid phobia and under-treatment of eczema are often more of a problem than over-treatment. Particular care should be taken on certain sites, such as the face and flexures, and in children and older adults (see Box 27.2 and Fig. 27.10).

The clinical features of eczema influence the choice of topical treatment. For example, appropriate treatment of acute exudative eczema could be with potassium permanganate soaks, emollients and topical glucocorticoids under wet wraps. Chronic eczema may be best treated with a potent topical glucocorticoid in an ointment formulation and occlusion with a paste bandage to ease itching and scratching.

The topical calcineurin inhibitors tacrolimus and pimecrolimus may be useful glucocorticoid-sparing agents for eczema, particularly on the face; they cause local cutaneous immunosuppression. Initial burning and stinging may limit use but are usually transient side-effects. Bacterial and viral skin infection risk may be increased due to immunosuppression. Caution should be employed with sun exposure and these agents should not be used in combination with phototherapy because of their immunosuppressive effects.

### Atopic eczema

This is the most common subtype of eczema. The prevalence has increased dramatically since the early 1980s, and the disease now affects at least 20% of schoolchildren and 5%–10% of adults in the UK.

### Pathogenesis

Generalised prolonged hypersensitivity to common environmental antigens, such as pollen and house-dust mite, is the hallmark of atopy, in which there is a genetic predisposition to produce excess IgE. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. Genetic factors play an important role in all of these conditions, supported by higher concordance of atopic disease in monozygotic twins compared with dizygotic twins. Filaggrin gene mutations increase the risk of developing atopic eczema by more than threefold, emphasising the importance of epidermal barrier impairment in this disease. Other genes are also likely to be implicated, with many other susceptibility loci identified, although these studies require further replication. Decreased skin barrier
function may also allow greater penetration of allergens through the epidermis, and thus cause immune stimulation and subsequent inflammation. The interaction between genes and environment is important; it has been estimated that 60%–80% of individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair. Eczema is characterised by infiltration of Th2 cells, which are known to play a role in activating mast cells and eosinophils, as well as stimulating IgE production by IgE-producing B cells. The therapeutic inhibition of IL-4 and IL-13 and promising trials of phosphodiesterase-4 and JAK inhibitors, highlights the involvement of these targets in atopic dermatitis pathogenesis. Emerging therapeutic targets for atopic eczema both in terms of targeting Th2-driven inflammation and skin barrier dysfunction is a rapidly evolving field and further informs our understanding at a mechanistic level (see Fig. 27.34). The contributing roles of the microbiome are also being explored. Thus, the pathogenesis of atopic eczema is complex and multifactorial, involving an interplay of contributing factors.

Clinical features
Atopic eczema is extremely itchy and scratching accounts for many of the signs (Fig. 27.33). Widespread cutaneous dryness (also known as xeroderma or xerosis) is another feature. The distribution and character of the rash vary with age (Box 27.20). Complications are listed in Box 27.21.

Investigations
The diagnosis of atopic eczema is made using clinical criteria (Box 27.22). Interestingly, while most patients with atopic eczema have raised total IgE levels and IgE-specific antibodies, this is not a prerequisite for the diagnosis, as a significant minority have normal levels of IgE.

Management
The general principles of management are as described in Figure 27.32. Emollients and topical glucocorticoids, tar and ichthammol paste bandages, or wet wraps in children, are often required and are mainstays in improving barrier function and reducing inflammation, although have not been shown to have a preventative effect against...
27.20 Atopic eczema: distribution and character of rash

Babies and infants
- Often acute and facial involvement prominent
- Trunk involved but nappy area usually spared

Children
- Flexures: behind knees, antecubital fossae, wrists and ankles

Adults
- Face and trunk usually involved, limb involvement not restricted to flexures
- Lichenification common

27.21 Complications of atopic eczema

Secondary infection
- Bacterial
  - Staphylococcus aureus most common
- Viral
  - Herpes simplex virus can cause a widespread severe eruption – eczema herpeticum
  - Papillomavirus and molluscum contagiosum are more common in atopic eczema, especially if treated with topical glucocorticoids

Increased susceptibility to irritants
- Defective barrier function

Increased susceptibility to allergy
- Food allergy – mainly relevant in infants: eggs, cow’s milk protein, nuts, fish, wheat and soya may cause an immediate reaction with angioedema and/or urticaria rather than exacerbation of eczema
- Anaphylaxis in severe allergy
- Increased risk of sensitisation to type IV allergens because of impaired barrier function

Impact on life and health
- Poor sleep, loss of schooling, behavioural difficulties, failure to thrive in children
- Impact on sleep, work, relationships, hobbies, psychology and quality of life in adults

27.22 Diagnostic criteria for atopic eczema

Itchy skin rash (or history of itch or rubbing from parent) and at least three of the following:
- History of involvement of skin creases (or cheeks if <4 years)
- History of atopic disease (asthma, hay fever) (or in a first-degree relative if <4 years)
- Dry skin (xeroderma)
- Visible flexural eczema (cheeks, forehead, outer limbs if <4 years)
- Onset in first 2 years of life

Avoided in children. Localised phototherapy may be used for eczema on hands and feet and PUVA may be more effective in that situation. Systemic immunosuppression with, for example, oral glucocorticoids, intermittent ciclosporin, azathioprine or methotrexate may be needed if the response to topical therapies and phototherapy is inadequate. Systemic retinoids, such as acitretin or alitretinoin, may be indicated: for example, in hand and foot eczema.

Dupilumab, which blocks the IL-4 receptor alpha chain subunit common to both IL-4 and IL-13 receptors, is now licensed for clinical use in patients with severe disease, as are the JAK inhibitors baricitinib and upadacitinib. The anti-IL-13 agents tralokinumab and lebrikizumab are also showing promise in clinical trials, as are phosphodiesterase-4 inhibitors and other therapeutic targets (see Fig. 27.11 and Box 27.14).

Seborrhoeic eczema

This is an erythematous scaly rash affecting the scalp (dandruff), central face, nasolabial folds, eyebrows, central chest and upper back. It is associated with, and may be due to, overgrowth of Malassezia yeasts. When severe, it may resemble psoriasis. Severe or recalcitrant seborrhoeic eczema can be a marker of immunodeficiency, including HIV infection. Topical azoles, such as ketoconazole shampoo and cream, often combined with mild glucocorticoid, are mainstays. Treatment often needs to be repeated due to disease recurrence.

Discoid eczema

Discoid eczema, which is also known as nummular eczema, is common and characteristically consists of discrete, coin-shaped eczematous lesions, which are often impetiginised and most commonly occur on the limbs of men. It is an eczema type that can be due to any chronic itchy condition, whether primarily of the skin or secondary to an underlying disease. Initial management should include topical antiseptics, in addition to emollients and topical glucocorticoids. Judicious antibiotic use may also be required for acute flares.

Irritant eczema

Detergents, alkalis, acids, solvents and abrasives are common irritants. Strong irritants have acute effects, whereas weaker irritants commonly cause chronic eczema, especially of the hands, after prolonged exposure. Individual susceptibility varies and older adults, atopic and fair-skinned individuals are predisposed. Irritant eczema accounts for most occupational cases of eczema and is a significant cause of time off work. Irritant avoidance, including protective clothing (such as gloves), is essential. Emollients and topical glucocorticoids are indicated.

Allergic contact eczema

This occurs due to a delayed hypersensitivity reaction following contact with antigens or haptons. Previous allergen exposure is required for sensitisation and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 27.23.

Allergy persists indefinitely and eczema occurs at sites of allergen contact and can secondarily spread beyond this. The distribution of eczema can be very informative with regard to possible culprits. There are many recognisable patterns of sites of eczema involvement, such as earlobes, wrists and umbilicus due to contact with nickel in earrings, watches and jeans studs; hands and wrists due to rubber gloves; and upper eyelids due to colophony from rubbing of the eyes in nail vanish wearners. Oedema may also be a feature (Fig. 27.34). Allergen avoidance is key and may involve a change of occupation, recreational activities or hobbies. It is important to ensure that patients are fully informed as to the nature and likely occurrence of allergens and good detective work is required to scrutinise lifestyle and daily activities. Treatment with emollients and topical glucocorticoids helps but will not suffice if there is continued allergen exposure.
are antihistamine Fig. 27.34 Allergic contact eczema. This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral peri-orbital oedema are typical.

Asteotic eczema

This occurs in dry skin and is common in older adults. Low humidity caused by central heating, over-washing, diuretics and cholesterol-lowering drugs predispose. The most common site is the lower legs, and a ‘crazy paving’ pattern of fine fissuring on an erythematous background is seen. Emollients are a mainstay, in combination with topical glucocorticoids. Patients must be advised to use caution with flammable emollients and to avoid bathroom slippages related to emollients on floor and feet, and this is particularly relevant for older individuals.

Gravitational eczema

Gravitational or stasis eczema occurs on the lower legs and is often associated with signs of venous insufficiency: oedema, loss of hair, induration, lipodermatosclerosis and ulceration. Emollients should be used and topical glucocorticoids should be applied to eczematous areas but not to ulcers. There is a high risk of sensitisation to topical preservatives (such as chlorocresol), antibiotics (such as neomycin) and bandages (such as rubber additives). Oedema and ulceration are treated by leg elevation and compression bandages.

Lichen simplex

Lichenification of eczema occurs secondary to chronic rubbing and scratching, and lichen simplex is a localised form. Common sites include the neck, lower legs and anogenital region. Treatment with emollients and very potent topical glucocorticoids may be required, often impregnated in tape or with occlusion.

Pompholyx

Intensely itchy vesicles and bullae occur on the palms, palmar surface and sides of the fingers and soles. Pompholyx may have several causes, which include atopic eczema, irritant and contact allergic dermatitis and fungal infection. The underlying cause must be treated or removed.

Psoriasis and other erythematous scaly eruptions

Psoriasis

Psoriasis is a chronic inflammatory, hyperproliferative skin disease. It is characterised by well-defined, erythematous scaly plaques, particularly affecting extensor surfaces, scalp and nails, and usually follows a relapsing and remitting course. Psoriasis affects approximately 1.5%–3% of populations of European ancestry but is less common in Asian, South American and African populations. It occurs equally in both sexes and at any age; although it is uncommon under the age of 5 years, more than 50% of patients present before the age of 30 years. The age of onset follows a bimodal distribution, with an early-onset type in the teenage or early adult years, often with a family history of psoriasis, a more severe disease course and strong HLA association. The later-onset type is typically seen between 50 and 60 years, usually without a family history and with a less severe disease course.

Pathogenesis

Both genetic and environmental factors are important. Twin studies show concordance rates of 60%–75% and 15%–20% for psoriasis arising in monozygotic and dizygotic twins, respectively. The age at onset and severity of disease are often similar in familial cases. If one parent has psoriasis, the chance of a child being affected is about 15%–20%; if both parents have the disease, this rises to 50% and the risk is increased further if a sibling also has the disease.

Variants of the HLA-C region within the major histocompatibility complex (MHC) on chromosome 6 account for almost half of the heritability of psoriasis. However, at least 70 other loci are implicated, with susceptibility variants that lie within or close to genes involved in regulating epidermal barrier function, antigen presentation, cytokine production, notably IL-13 and IL-23, T-cell differentiation (especially Th-1 and Th-17 subsets) and nuclear factor kappa B (NFkB) signalling. Some of the loci that predispose to psoriasis overlap with those implicated in Crohn’s disease, ankylosing spondylitis and psoriatic arthritis.

Environmental triggers for psoriasis are shown in Box 27.24. Although the theory is controversial, stress may exacerbate psoriasis in susceptible individuals and psoriasis is itself a cause of psychological stress. Likewise, there is a higher incidence of smoking and heavy alcohol consumption in patients with psoriasis but it is unclear whether this is cause or effect. There is also an association between psoriasis and metabolic syndrome.

The histological changes of psoriasis are shown in Figure 27.35. The main features are:

- keratinocyte hyperproliferation and abnormal differentiation, leading to retention of nuclei in the stratum corneum
immunological factors play a key role in psoriasis, the precise mechanisms of disease initiation and the sequence of events that lead to psoriasis are not fully defined. Therapeutic efficacy through targeted biological inhibition of the effects of key cytokines, notably TNF-α, IL-17, IL-23 and IL-12, continues to provide major insight into the pathogenesis of psoriasis and the pathways and mechanisms involved.

### Clinical features
Psoriasis has several different presentations (Fig. 27.36).

#### Plaque psoriasis
This is the most common presentation and usually represents more stable disease. The typical lesion is a raised, well-demarcated erythematous plaque of variable size (see Fig. 27.36A). In untreated disease, silver/white plaque is evident and more obvious on scraping the surface, which reveals bleeding points (Auspitz sign). The most common sites are the extensor surfaces, notably elbows and knees, and the lower back. Others include:

- **Scalp:** involvement is seen in approximately 60% of patients. Typically, easily palpable, erythematosus scaly plaques are evident within hair-bearing scalp and there is clear demarcation at or beyond the hair margin. Occipital involvement is common and difficult to treat. Less often, fine diffuse scaling may be present and difficult to distinguish from seborrheic dermatitis. Involvement of other ‘seborrheic sites’, such as eyebrows, nasolabial folds and the pre-ternal area, is not uncommon and again may be confused with seborrheic dermatitis. Temporary hair loss can occur but permanent loss is unusual.

- **Nails:** involvement is common, with ‘thimble pitting’, onycholysis (separation of the nail from the nail bed, see Fig. 27.36B), subungual hyperkeratosis and periungual involvement.

- **Flexures:** psoriasis of the natal cleft and submammary and axillary folds is usually symmetrical, erythematous and smooth, without scale.

- **Palms:** psoriasis of the palms can be difficult to distinguish from eczema.

#### Guttate psoriasis
This is most common in children and adolescents and is often the initial presentation (see Fig. 27.36C). It may present shortly after a streptococcal throat infection and evolves rapidly. Individual lesions are drop-shaped, small (usually less than 1 cm in diameter), erythematous, scaly and numerous. An episode of guttate psoriasis may be spontaneous or with topical treatment within a few months, but UVB phototherapy is often required and is highly effective. Guttate psoriasis often heralds the onset of plaque psoriasis in adulthood.

#### Erythrodermic psoriasis
Generalised erythrodermic psoriasis is a medical emergency (see Fig. 27.36D).

---

**Fig. 27.35** The histology of psoriasis.
Pustular psoriasis

Pustular psoriasis may be generalised or localised. Generalised pustular psoriasis is uncommon, unstable and life-threatening. It will often emerge in the context of plaque disease and the onset is usually sudden, with large numbers of small, sterile pustules on an erythematous background, often merging into sheets, with waves of new pustules in subsequent days. The patient is usually febrile and systemically unwell, and this must be dealt with as a medical emergency. Unstable pustular psoriasis may be precipitated as a rebound phenomenon following either topical or systemic glucocorticoid use in a patient with psoriasis. Localised pustular psoriasis of the palms and soles (palmoplantar pustulosis) is more common, chronic and closely associated with smoking: small, sterile pustules and erythema develop and resolve with pigmentation and scaling. A localised form of sterile pustulosis of a few digits (acropustulosis) can also occur. It is unclear whether these localised forms of pustulosis are truly psoriatic.

Arthropathy

Between 5% and 10% of individuals with psoriasis develop an inflammatory arthropathy, which can take on a number of patterns. Joint involvement is more likely in patients with psoriatic nail disease. Psoriatic arthritis is discussed in more detail in Chapter 26.

Investigations

Skin biopsy is not usually required but may be performed if there is diagnostic doubt. An infection screen, particularly throat swab and/or serology for recent streptococcal infection, may be informative in guttate psoriasis. Assessment of impact on life using the DLQI and disease extent using PASI (Psoriasis Area and Severity Index) is essential. Due to the association of psoriasis with metabolic syndrome, comorbidities and cardiovascular risk factors should be assessed and managed along usual lines. HIV testing should be considered in severe or recalcitrant psoriasis.

Management

Counselling about diagnosis and management of skin involvement and other comorbidities is paramount. Information and services must be available for patients. Psoriasis can have a major impact on all aspects of life and this must not be under-estimated. Reassurance is also needed, as the condition is generally not life-threatening. Advice regarding reduction in risk factors for cardiovascular disease should be given (smoking cessation, reduction of alcohol intake, adequate exercise and a normal body mass index). Associated diseases, such as hypertension and diabetes, should be treated.

Patients need to be involved in their own management, as the disease is usually chronic and the benefit/risk profile of treatments must be
discussed and tailored to individuals. The endpoint for treatment also needs to be discussed because complete disease clearance may not be practical or appropriate and patients vary considerably in their treatment requirements. Extent of disease and impact on quality of life must be taken into account. Patient adherence to topical and systemic therapies is essential and dependent on the treatment practicalities.

The treatment approach generally follows a stepwise progression, with treatment categories broadly summarised (Fig. 27.37).

Topical treatments, including emollients, are the first-line approach. Vitamin D receptor agonists, such as calcipotriol, calcitriol and tacalcitol, are often used as first-line topical treatment. The mechanism of action includes increased differentiation and reduction of proliferation, reducing plaque scale and thickness. Calcipotriol is most widely used and can be applied once to twice daily; if less than 100 g of ointment is used each week, there is no risk of hypercalcemia. Vitamin D analogues can cause irritation but this is often temporary. Topical glucocorticoids may be required in the management of psoriasis, particularly at flexural sites or facial sites, and may be alternated or combined with vitamin D analogues. However, safe, appropriately supervised and judicious use is necessary, with awareness of the potential risk of rebound unstable or pustular psoriasis with glucocorticoid over-use or sudden cessation. Dithranol and coal tar are effective and, like vitamin D analogues, work by increasing differentiation and inhibiting proliferation. Although often effective, they are messy and time-consuming. Modified versions of Goeckerman’s regimen (the combination of coal tar and UVB) are still used, but coal tar has a characteristic odour and can be irritant. Short-contact dithranol therapy at relatively high concentrations applied for 15–30 minutes can be used but causes brown staining of skin and purple discoloration of light hair. In recent years, efforts have been made to improve the tolerance of tar and dithranol preparations, but at reduced efficacy. Overall, the use of tar and dithranol has reduced in recent years but they can be highly effective in selected patients.

If topical treatment is insufficient, then UVB phototherapy or PUVA should usually be the next step. If the patient continues to have active disease or early recurrence, then the addition of systemic retinoid such as acitretin to UVB or PUVA can be effective. Alternatively, immunosuppressants, such as methotrexate or ciclosporin, may be required. For difficult treatment-resistant disease, fumaric acid esters, apremilast and biologics should be considered and biologic therapies are now widely used in routine dermatology practice and have had a major impact on the management of patients with severe or poorly responsive psoriasis (see Fig. 27.11 and Box 27.14).

The active component of fumaric acid ester therapy is dimethyl fumarate and efficacy in psoriasis is established. Common adverse effects are flushing and diarrhoea. Lymphopenia is also expected at effective doses. Apremilast (a phosphodiesterase-4 inhibitor) is indicated for moderate to severe psoriasis resistant to standard measures (such as light-based therapies, methotrexate or ciclosporin). Of the biologic agents, the anti-TNF-α agents (adalimumab, etanercept, infliximab, certolizumab), ustekinumab (an inhibitor of IL-12 and IL-23), guselkumab (IL-23 inhibitor) and secukinumab, brodalumab, ixekizumab or bimekizumab (IL-17 inhibitors) may all offer higher levels of efficacy.

Irrespective of the treatment chosen, individualised management is essential. For example, a patient with localised plaque psoriasis on elbows, knees and sacrum should respond to topical treatment only, whereas someone with guttate psoriasis is likely to need phototherapy as a first-line approach because of difficulties in topical drug application in extensive disease. A patient with extensive chronic plaque psoriasis and significant arthropathy would be better suited to a systemic drug, such as methotrexate, than phototherapy, which would be unlikely to improve joint symptoms. Thus, whilst a stepwise general approach to management (see Fig. 27.37) may offer guidance, the correct choice for any given patient must be determined on an individual basis.

### Pityriasis rosea

This is an acute, self-limiting exanthem that particularly affects young adults and occurs worldwide, with a slight female predominance. It usually presents in spring and summer, although no infective agent has been identified and its aetiology is unknown. It is characterised by the appearance of a “herald patch”, an oval lesion (1–2 cm) with a pinkish (salmon-coloured) centre, a darker periphery and a characteristic collarette of scale. It is followed 1–2 weeks later by a widespread papulosquamous eruption, which is typically arranged in a symmetrical ‘fir tree’ pattern on the trunk. Individual lesions also have a collarette of scale. An inverse variant with flexural involvement can occur. Mucosal involvement is rare. There is a small risk of recurrence. Symptomatic relief can be achieved with emollients and mild topical glucocorticoids. Post-inflammatory hyperpigmentation can supervene, particularly in darker skin types.

### Pityriasis lichenoides chronica

This is rare but typically presents within the first three decades of life. The aetiology is unclear but the condition is part of a spectrum and remits spontaneously. The more acute variety (pityriasis lichenoides et varioliformis acuta, PLEVA) presents as crops of papules that rapidly evolve with central necrosis, each attack lasting up to 3 months. The more chronic variety presents as a persistent, widespread, scaly...

---

**Fig. 27.37 General management approaches: psoriasis.** (IL = interleukin; PUVA = psoralen-ultraviolet A; TNF-α = tumour necrosis factor alpha; UVB = ultraviolet B)
eruption. Characteristically, lesions are brown papules with a mica-like scale (‘cornflake’). The condition fluctuates but can persist for months or years. Emollients, topical glucocorticoids and long-term oral erythromycin can occasionally be helpful. UVB phototherapy or PUVA is usually effective, although recurrences are high.

### Drug eruptions

It is essential to consider a drug cause in anyone presenting with an erythematous maculopapular or papulosquamous eruption, and a careful drug history is critical. Exfoliation (‘peeling’) and post-inflammatory hyper- or, less commonly, hypopigmentation can occur.

### Other causes

Secondary syphilis, pityriasis versicolor and tinea corporis fungal infection can all cause an erythematous papulosquamous rash and must be considered in the differential diagnosis of erythematous papulosquamous rashes.

### Lichenoid eruptions

#### Lichen planus

Lichen planus occurs worldwide. It typically presents as a pruritic rash; the mucosa, hair and nails may also be involved.

**Pathogenesis**

The disease probably has an autoimmune basis since there is an association with inflammatory bowel disease, primary biliary cholangitis, autoimmune hepatitis, hepatitis B and C, alopecia areata, myasthenia gravis and thymoma. There are also similarities with graft-versus-host disease (GVHD). Lichen planus can occasionally occur in families and possible HLA associations have been reported but there is no clear inheritance pattern. On skin biopsy, characteristic histological changes include hyperkeratosis, basal cell degeneration and a heavy, band-like T-lymphocyte infiltrate in the papillary dermis, with affinity for the epidermis (epidermotropism). The dermo-epidermal junction has a ‘sawtooth’ appearance.

**Clinical features**

Lichen planus occurs in both sexes and at any age, although usually between 30 and 60 years. It generally presents on the distal limbs, most commonly on the flexural aspects of the wrists and forearms (Fig. 27.38), and on the lower back. It is intensely itchy and lesions are violaceous, shiny, flat-topped, polygonal papules, with a characteristic fine lacy, white network on the surface (Wickham’s striae). New lesions may appear at sites of skin trauma (Köbner phenomenon) and the rash may become generalised. Individual lesions may last for many months and can become hypertrophic and modified by scratching, particularly on the lower legs.

The eruption usually remits over months but can become chronic, particularly with hypertrophic disease. Post-inflammatory pigmentation change is common, particularly in darker skin types. Mucous membrane involvement occurs in 30%–70% of patients, usually as a network of white, lacy striae on the buccal mucosa and tongue. These oral changes are often asymptomatic and should be sought on examination. Genital and other mucosal surfaces can also be affected. Nail involvement occurs in about 10% and can range from longitudinal ridging to a destructive nail dystrophy, scarring (pterygium) and nail loss. Scalp involvement usually presents as an inflammatory scarring alopecia, often with tufting of residual hairs. The classical presentation of lichen planus is unmistakable, but less common atypical variants, which include annular, atrophic, actinic, linear, bullous, follicular, pigmented and ulcerative types, can be a diagnostic challenge.

**Investigations**

A skin biopsy should be performed if there is diagnostic doubt. A careful drug history must be taken, as, although the classical presentation of lichen planus is usually ‘idiopathic’, the main differential is a drug-induced lichenoid reaction (see below). Other differential diagnoses include psoriasis, pityriasis rosea, pityriasis lichenoides chronic and secondary syphilis. Screening for underlying disease, such as hepatitis, must be considered.

**Management**

The condition is usually self-limiting, although rarely it may persist for years, particularly oral lichen planus. Treatment is symptomatic and potent local glucocorticoids (topical, with occlusion or by injection for hypertrophic disease, or as oral rinse for oral involvement) may help the intense itch; short courses of systemic glucocorticoids are sometimes required for extensive disease. UVB, PUVA or UV A1 can be beneficial and, for recalcitrant disease, retinoids or immunosuppressants, such as ciclosporin or methotrexate, may be needed. A low but significant risk of malignant transformation exists with persistent oral and genital disease, so active treatment, surveillance and smoking cessation are important.

#### Drug-induced lichenoid eruptions

Drug-induced lichenoid reactions that are clinically and histologically difficult to distinguish from idiopathic lichen planus are important to identify. The likely culprits are gold, quinine, proton pump inhibitors, sulphonamides, penicillamine, antimalarials, antituberculous drugs, thiazide diuretics, β-adrenoceptor antagonists (β-blockers), angiotensin-converting enzyme (ACE) inhibitors, NSAIDs, sulphhydrylues, lithium and dyes in colour developers (see Box 27.36).

#### Graft-versus-host disease

In the acute stage of graft-versus-host disease (GVHD), there is a distinctive dermatitis associated with hepatitis. After about 3 months, chronic GVHD can present with a lichenoid eruption on the palms, soles, face and upper trunk. Progressive sclerodermatous skin thickening, associated with pigmented changes, may lead to contractures and limited mobility.

### Urticaria

Urticaria (‘hives’) is caused by localised dermal oedema secondary to a temporary increase in capillary permeability. If oedema involves subcutaneous or submucosal layers, the term angioedema is used.

#### Clinical features

Acute urticaria may be associated with angioedema of the lips, face, tongue, throat and, rarely, wheezing, abdominal pain, headaches and even anaphylaxis. Urticaria present for less than 6 weeks is considered to be acute, and chronic if it continues for more than 6 weeks. Individual weals can resolve within minutes, while new weals may arise. Erythematous macules, papules, plaques and plaques – Fig. 27.39) last for less than 24 hours; if
they persist, urticarial vasculitis needs to be considered. Clarification of the duration of urticaria can be achieved by drawing around the weal and reassessing 24 hours later. History-taking should probe for possible causes, including medications (Box 27.25). Physical triggers can also be assessed in challenge testing, such as eliciting dermographism or pressure testing. Enquiry about family history and medication, particularly ACE inhibitors, is important in angioedema. Examination may be unremarkable or weals may be evident (see Fig. 27.39). The skin should be stroked firmly with an orange stick in order to ascertain whether dermographism is present or not.

Mast cell degranulation and release of histamine and other vasoactive mediators is the basis of urticaria (Fig. 27.40). Chronic spontaneous urticaria (previously called ‘chronic idiopathic’ or ‘chronic ordinary’ urticaria) is the most common chronic urticaria and has an autoimmune pathogenesis in some cases.

**Investigations**

Investigations should be guided by the history and possible causes, but are often negative, particularly in acute urticaria. Some or all of the following may be appropriate:

- **Full blood count**: eosinophilia in parasitic infection or drug cause.
- **Erythrocyte sedimentation rate (ESR) or plasma viscosity**: elevated in vasculitis.
- **Urea and electrolytes, thyroid and liver function tests, iron studies**: may reveal an underlying systemic disorder.
- **Total IgE and specific IgE to possible allergens**: shellfish, peanut, house-dust mite. Particularly relevant if there is angioedema.
- **Autoantibodies, particularly antinuclear factor**: positive in systemic lupus erythematosus (SLE) and often positive in urticarial vasculitis. Other autoimmune diseases, such as rheumatoid arthritis and autoimmune hepatitis or thyroid disease, may be associated.
- **Complement C3 and C4 levels**: if these are low due to complement consumption, C4 esterase inhibitor activity should be measured.
- **Infection screen**: hepatitis screen and HIV may be indicated.
- **Skin biopsy**: if urticarial vasculitis is suspected.
- **Challenge tests**: to confirm physical urticarias, such as dermographism, pressure, heat, cold.

**Management**

Removal or treatment of any trigger is essential, although this may not be identified in the majority of cases. Urticaria may be precipitated by aspirin, NSAIDs, codeine and opioids, and it is advisable to suggest alternatives such as paracetamol. In chronic urticaria, non-sedating

---

**Fig. 27.39** Urticaria. Erythema, reflecting dilated dermal vessels, and oedema (with upper dermal oedema obscuring the erythema centrally) are evident. Note the absence of epidermal changes.

**Urticarial vasculitis**

- Hepatitis B, SLE, idiopathic

(IGE = immunoglobulin E; SLE = systemic lupus erythematosus)

---

**Fig. 27.40** Pathogenesis of urticaria. Mast cell degranulation occurs in a variety of ways. (1) Type I hypersensitivity causes degranulation. (2) Spontaneous mast cell degranulation in chronic urticaria. (3) Chemical mast cell degranulation. (4) Autoimmunity, with IgE antibodies directed against IgE receptors or IgE itself. Histamine and the leukotrienes are especially relevant mediators in urticaria. Heparin release is probably not a major factor in urticaria but plays a role in the osteoporosis that can occur in systemic mastocytosis. (IGE = immunoglobulin E; NSAIDs = non-steroidal anti-inflammatory drugs)
antihistamines, such as fexofenadine, loratadine or cetirizine, are usually beneficial. If there is lack of response after 2 weeks, an alternative non-sedating antihistamine should be used and an \( \text{H}_2 \)-blocker, such as cimetidine or ranitidine, can be added. Mast cell stabilisers or leukotriene receptor antagonists, such as montelukast, can be used for more recalcitrant disease. For chronic urticaria, narrowband UVB phototherapy is valuable and has proven efficacy. Systemic glucocorticoids are widely prescribed for urticaria but are not indicated in the majority of cases. If systemic glucocorticoids are used, efficacy may be seen only at relatively high doses and they are appropriate only for occasional short courses in the acute setting, usually in association with angioedema. Patients with a history of life-threatening anaphylaxis, as in peanut or wasp sting allergy, should carry a self-administered adrenaline (epinephrine) injection kit. The management of anaphylaxis is discussed in Chapter 9 and the management of hereditary angioedema is discussed in Chapter 4. The anti-IgE monoclonal antibody omalizumab may be effective in patients with severe recalcitrant urticaria (Fig. 27.40).

### Bullous diseases

Blistering can occur at any level in the skin and there are a variety of different presentations, depending on the underlying defect and level of involvement. Knowledge of the molecular basis of many blistering disorders has advanced considerably through understanding of the basic processes of cell adhesion and studies of rare genetic blistering disorders, particularly epidermolysis bullosa (Box 27.26). This section concentrates on primary blistering skin diseases.

### Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is a medical emergency, as the extensive mucocutaneous blistering is associated with a high mortality rate. It is usually drug-induced (see Box 27.36), with anticonvulsants, sulphonamides, sulphonyleureas, NSAIDs, allopurinol and antiretroviral therapy often implicated. Usually 1–4 weeks after drug commencement, the patient becomes systemically unwell and often pyrexial. Erythema and blistering develop, initially on the trunk but rapidly involving all skin; an early warning sign is cutaneous pain. Sheets of blisters coalesce and denude, and the underlying skin is painful and erythematous (Fig. 27.41). Gentle lateral pressure on stroking the skin results in epidermal detachment (Nikolsky sign), demonstrating the severity of skin fragility. Mucous membrane involvement and blistering are usual. Blistering of skin and mucceae may be haemorrhagic. A disease severity score (Box 27.27) is used to predict outcome. The main differential diagnosis is staphylococcal scalded skin syndrome, although the diagnosis is usually obvious in an adult patient with a culprit drug. There is often overlap with Stevens–Johnson syndrome and targetoid lesions, especially on palms and soles, may be evident. Skin snip may allow early diagnosis. If there is diagnostic doubt, then full-thickness skin biopsy should be undertaken for histology and direct immunofluorescence in order to exclude immunobullous or other diagnoses.

### Classification of epidermolysis bullosa

*See Figure 27.1.

Identification and discontinuation of the causative drug are essential. Sepsis and multi-organ failure are major risks. Intensive care in a dedicated dermatology ward or intensive care or burns unit is of paramount importance. Treatment is supportive, with regular sterile dressings and emollients, careful attention to fluid balance and treatment of infection if it develops. Urethral and ocular involvement is common and must be looked for and treated symptomatically. Chronic sequelae, including ocular and urethral scarring and adverse psychological impact can be problematic in survivors. There is no conclusive evidence that intravenous immunoglobulins, systemic glucocorticoids or ciclosporin improve outcomes and survival.
**Immunobullous diseases**

There are various subtypes of immunobullous disease that affect patients of different ages and have clinical characteristics (Box 27.29). The key investigation is an elliptical biopsy taken from the edge of a recent blister (Box 27.29). The sample is halved: one half is put in formalin for subsequent histology, while the other is sent fresh for direct immunofluorescence. Serum should also be sent for indirect immunofluorescence in suspected immunobullous disease.

**Bullous pemphigoid**

Bullous pemphigoid (BP) is the most common immunobullous disease and occurs worldwide. It is a disease of older people, with an average age of onset of 65 years; males and females are equally affected.

**Pathogenesis**

The disease is caused by autoantibodies (BP-230 and BP-180) directed against the hemi-desmosomal BP antigens BPAG-1 (intracellular) and BPAG-2 (transmembranous type XVII collagen), respectively. Antibody-antigen binding initiates complement activation and inflammation, with hemi-desmosomal damage and subepidermal blistering.

**Clinical features**

There is often a lengthy prodrome of an itchy, urticated, erythematous rash prior to the development of tense bullae (Fig. 27.42A). Milia (definition: small epidermal keratin cysts) may develop due to basement membrane disruption. Mucosal involvement is uncommon.

**Investigations**

The diagnosis can be made by skin biopsy, which shows subepidermal blistering with an eosinophil-rich inflammatory infiltrate. Direct immunofluorescence demonstrates the presence of IgG and C3 at the basement membrane (Fig. 27.42B). Indirect immunofluorescence may show positive titres of circulating anti-epidermal antibodies. Distinction from epidermolysis bullosa acquisita requires immunofluorescence studies using the patient’s serum on salt-split skin. In BP, the immunoreactants localise to the epidermal side (hemi-desmosome) of split skin, whereas in epidermolysis bullosa acquisita they localise to the base of the split (type VII collagen/anchoring fibrils).

**Management**

Very potent topical glucocorticoids are effective and may be sufficient in frail older patients; they need to be applied to all sites, however, and not just lesional skin. Tetracyclines, such as doxycycline, have important anti-inflammatory effects and may limit the use of systemic glucocorticoids. Doxycycline has been shown to be non-inferior to prednisolone for initial control of bullous pemphigoid and to have fewer long-term adverse effects, although most patients with extensive disease will go on to require systemic glucocorticoids (0.75 mg/kg/day or less), often combined with immunosuppressants as glucocorticoid-sparing agents. In severe refractory disease, other therapies, such as intravenous immunoglobulin or rituximab, are sometimes used but are of unproven efficacy. The condition does, however, often burn out spontaneously over a few years.

(BMZ = basement membrane zone; IF = immunofluorescence; Ig = immunoglobulin)
Pemphigus

Pemphigus is less common than BP and patients tend to be younger.

Pathogenesis

The cause is IgG1 and IgG4 autoantibodies, directed against desmogleins-1 and 3, resulting in intra-epidermal blistering. The syndrome may occur spontaneously or be secondary to drugs such as penicillamine or captopril and underlying malignancy (paraneoplastic pemphigus). Pemphigus foliaceus is a very superficial form, in which antibodies are directed against desmoglein-1 only and affect just the most superficial epidermis.

Clinical features

Skin and mucosae are usually involved, although disease may be restricted to mucosae only, which may be severely affected. Due to the higher level of split within the epidermis, the blisters are flaccid, easily ruptured and often not seen intact. Erosions are common and the Nikolsky sign is positive. The trunk is usually affected. The condition is associated with significant morbidity and mortality.

Investigations

The diagnosis can be made by skin biopsy, which shows intra-epidermal blistering and acantholysis, with positive direct immunofluorescence for IgG (usually IgG1 or IgG4) and C3 at the periphery of keratinocytes, giving a ‘chicken wire’ appearance within the epidermis. The titres of circulating epidermal autoantibodies can also be used to monitor disease activity. Investigations should screen for associated autoimmune disease or malignancy if paraneoplastic pemphigus is suspected.

Management

Pemphigus is more difficult to treat than BP and high-dose systemic glucocorticoids such as prednisolone (0.5–1.0 mg/kg/day) are usually required. Azathioprine and cyclophosphamide are most often used as glucocorticoid-sparing agents but a range of other immunosuppressants may be considered for severe recalcitrant disease, including methotrexate, ciclosporin, mycophenolate mofetil, intravenous immunoglobulins, plasma exchange, extracorporeal photopheresis and rituximab. Often, long-term treatment is required to prevent relapse.

Dermatitis herpetiformis

Dermatitis herpetiformis (DH) is an autoimmune blistering disorder that is strongly associated with coeliac disease (CD). While fewer than 10% of individuals with CD develop DH, almost all patients with DH have evidence of partial villous atrophy on intestinal biopsy, even if they have no gastrointestinal symptoms. It is unclear why some CD patients develop DH and others do not. Although DH is a bullous disease, intact vesicles and blisters are seldom seen, as the condition is so pruritic that excoriations on extensor surfaces of arms, knees, buttocks, shoulders and scalp may be the only signs.

The diagnosis can be made by skin biopsy, which shows subepidermal vesiculation in the dermal papillae and a neutrophil- and eosinophil-rich infiltrate. Direct immunofluorescence shows granular IgA in the papillary dermis. Anti-endomysial antibodies and tissue transglutaminase should be assessed and jejunal biopsy undertaken if indicated. The condition usually responds to a gluten-free diet but, if not, dapsone can also be used.

Linear IgA disease

This occurs in children (chronic bullous disease of childhood) and adults, and is usually self-limiting, although it can be active for a few years. Drugs, notably vancomycin, can be a secondary cause. Blisters can arise on erythematous, urticated or otherwise normal-looking skin and often form an annular configuration at the edge of the lesion: ‘clusters of jewels’ (herpetiform) and ‘string of beads’ (annular/polycyclic). Mucosal involvement is common and ophthalmology input important, as corneal scarring is a risk with longstanding disease. Linear IgA is seen at the basement membrane on direct immunofluorescence and localises to either roof or floor of skin split skin. Dapsone, sulfapyridine, prednisolone, colchicine or intravenous immunoglobulin may be effective.

Epidermolysis bullosa acquisita

This chronic blistering disease affects skin and mucosae, and scarring, hair loss and nail dystrophy may be problematic. Blisters often follow trauma and milia develop. It can be very difficult to distinguish from other immunobullous diseases, such as bullous pemphigoid. It is caused by an IgG antibody to type VII collagen, which provokes subepidermal blistering and a mixed inflammatory infiltrate, although the latter may not be prominent. Direct immunofluorescence on perilesional skin shows IgG and C3 at the dermo-epidermal junction and pattern analysis may be helpful in distinction from bullous pemphigoid. Indirect immunofluorescence microscopy on salt-split normal human skin typically shows IgG and IgA in the floor of the artificially induced blister, whereas in BP antibody localisation would be to the roof of the blister. Epidermolysis bullosa acquisita is very difficult to treat, as it often does not respond well to immunosuppressants. Mainstays of treatment include systemic glucocorticoids in combination with dapsone or colchicine. Other immunosuppressive approaches may be required and include ciclosporin, azathioprine, immunoglobulins, plasmapheresis and rituximab. The condition may be associated with inflammatory bowel disease, rheumatoid arthritis, multiple myeloma and lymphoma, and thus associated comorbidities should be sought.
Porphyria cutanea tarda and pseudoporphyria

These conditions may also cause blistersing (see Boxes 27.9 and 27.35). Porphyria is discussed in more detail in Chapter 19.

**Pigmentation disorders**

**Decreased pigmentation**

Disorders causing hypopigmentation and/or depigmentation include:

- vitiligo
- albinism
- pityriasis alba: depigmented areas on the face, particularly in children, with or without scale and usually considered to be eczematous
- pityriasis versicolor: hypopigmentation or, less commonly, hyperpigmentation can occur
- idiopathic guttate hypomelanosis: multiple small areas of depigmentation arising in chronically sun-exposed skin
- rarely, phenylketonuria and hypopituitarism.

**Vitiligo**

Vitiligo is an acquired condition affecting 1% of the population worldwide. Focal loss of melanocytes results in the development of patches of hypopigmentation. A positive family history of vitiligo is relatively common in those with extensive disease, and this type is also associated with other autoimmune diseases. Trauma and sunburn may (through the Köbner phenomenon) precipitate the appearance of vitiligo. It is thought to be the result of cell-mediated autoimmune destruction of melanocytes but why some areas are targeted and others are spared is unclear.

**Clinical features**

Generalised vitiligo is often symmetrical and involves hands, wrists, feet, knees and neck, as well as areas around body orifices (Fig. 27.43). The hair of the scalp, beard, eyebrows and lashes may also depigment. Segmental vitiligo is restricted to one part of the body but not necessarily a dermatome. The patches of depigmentation are sharply defined, and in light-skinned individuals may be surrounded by hyperpigmentation. Spotty perifollicular pigment may be seen within the depigmentation and is often the first sign of repigmentation. There is no history or evidence of inflammation within the patches, which may be helpful in distinguishing vitiligo from post-inflammatory hypopigmentation. Sensation in the depigmented patches is normal, unlike tuberculoed leprosy. Wood's light examination enhances the contrast between pigmented and non-pigmented skin. The course is unpredictable; most patches remain static or enlarge but a few undergo re-pigmentation spontaneously.

**Management**

Protecting the patches from excessive sun exposure with clothing or sunscreen may be helpful to avoid sunburn. Camouflage cosmetics may be beneficial, particularly in those with dark skin. In fair skin, photoprotection and cosmetic cover may be all that is required. Very potent or potent topical glucocorticoids have limited efficacy with respect to repigmentation. Topical pimecrolimus or tacrolimus may also have a role as a glucocorticoid-sparing agent. Phototherapy with narrowband UVB or PUVA can also be used. Narrowband UVB is the most effective regimens treatment available for generalised vitiligo, but even very prolonged courses often do not produce a satisfactory outcome. The absence of leukotrichia (white hairs in the area of vitiligo) and the presence of a trichrome pattern (three colours - normal skin colour, hypopigmentation and depigmentation) are good prognostic features. Vitiligo on the face, trunk and proximal limbs is more likely to respond than that on hands and feet. Exceptionally, depigmentation of normal non-lesional skin or a surgical approach with autologous melanocyte transfer, using a range of techniques including split-skin grafts and blister roof grafts, is sometimes used on dermabraded recipient skin in specific severe cases.

| Fig. 27.43 Vitiligo. Symmetrical depigmentation of the knees and lower extremities. The dorsal aspect of the feet and hands are particularly hard to repigment. From Mancini AJ, Paller AS. Hurwitz clinical pediatric dermatology, 5th edn. Elsevier; 2016. |

The impact of vitiligo differs markedly between populations. In South Asia the effects are more readily discernible than in light-skinned individuals in northern Europe. Depigmentation is also seen in leprosy, which means that individuals with vitiligo are often stigmatised. The emotional impact of vitiligo may be immense; psychological support is essential and is important in conveying realistic expectations of possible treatment approaches.

**Oculocutaneous albinism**

Albinism results from a range of genetic abnormalities that lead to reduced melanin biosynthesis in the skin and eyes; the number of melanocytes is normal (in contrast to vitiligo). Albinism is usually inherited as an autosomal recessive trait and there are several different types and presentations.

Type 1 albinism is due to a defect in the tyrosinase gene, whose product is rate-limiting in the production of melanin. Affected individuals have an almost complete absence of pigment in the skin and hair at birth, with consequent pale skin and white hair, and failure of melanin production in the iris and retina. Patients have photophobia, poor vision not correctable with refraction, rotatory nystagmus, and an alternating strabismus associated with abnormalities in the decussation of nerve fibres in the optic tract.

A second form of albinism is due to a defect in the P gene, which encodes an ion channel protein in the melanosome. Patients may have gross reduction of melanin in the skin and in the eyes, but may be more mildly affected than type 1 albinos. Establishing the subtype of albinism requires genetic analysis, as there is considerable phenotypic heterogeneity.

Oculocutaneous albinos are at grossly increased risk of sunburn and skin cancer. In equatorial regions, many die from squamous cell carcinoma or, more rarely, melanoma in early adult life. Interestingly, they may develop pigmented melanocytic naevi and freckles in response to sun exposure.

**Management**

Strict photoprotection, with sun avoidance (including occupational exposure), clothing, hats and sunscreens, is important. Early diagnosis and treatment of skin tumours is essential.
Increased pigmentation

- **Diffuse hyperpigmentation:** most commonly due to hypermelanosis but other pigments may be deposited in the skin, such as orange discoloration with carotenemia and bronze with haemochromatosis.
- **Endocrine pigmentation:** may occur in several conditions. Melasma (chloasma) describes discrete patches of facial pigmentation that occur in pregnancy and in some women taking oral contraceptives. The mechanism for this localised increased hormonal sensitivity is unknown. Diffuse pigmentation, sometimes worse in the skin creases and mucosas, may be a feature of Addison’s disease, Cushing’s syndrome, Nelson syndrome and chronic renal failure due to increased levels of pituitary melanotrophic peptides, including adrenocorticotropic hormone (ACTH).
- **Photo-exposed site hyperpigmentation:** occurs in some of the porphrias but can also be drug-induced with amiodarone and chlorpromazine.
- **Drug-induced pigmentation** (Box 27.30): may be diffuse or localised. It is not always due to hypermelanosis but sometimes is caused by deposition of the drug or a metabolite.
- **Focal hypermelanosis:** seen in lesions such as freckles and lentigines, characterised by focal areas of increased pigmentation.

Establishing the cause is important. Photoprotection may minimise the risk of increasing pigmentation. Topical hydroquinone preparations can be used for skin lightening in some types of hyperpigmentation, although caution is required, particularly in darker skin types.

Hair disorders

These can be subdivided into disorders that cause loss of hair (alopecia) or excessive hair growth (hypertrichosis and hirsutism).

Alopecia

Alopecia is characterised by loss of hair. It can be further subdivided into localised and diffuse, and into scarring and non-scarring subtypes (Box 27.31).

Pathogenesis

Alopecia can be observed in association with inflammatory disorders that cause scarring (lichen planus, discoid lupus) and others that do not cause scarring (tinea capitis, psoriasis, seborrhoeic eczema). These conditions are discussed elsewhere. Alopecia areata has an autoimmune basis and there is a strong genetic component, with a family history in approximately 20% of cases. In addition to atopy, it is associated with other autoimmune diseases, particularly thyroid disease, and with Down syndrome. The cause of androgenetic alopecia is unclear but likely to be multifactorial, with genetic, hormonal and end-organ receptor sensitivity to the factors implicated. Developments in therapeutic approaches, such as JAK inhibition, will continue to provide evidence to inform our understanding of the pathogenesis of alopecia areata and the pathways involved.

Clinical features

Alopecia areata

This usually presents with well-defined, localised, non-inflammatory, non-scarring patches of alopecia, usually on the scalp (Fig. 27.44). Pathognomonic ‘exclamation mark’ hairs are seen (broken hairs, tapering towards the scalp) during active hair loss. A diffuse pattern can uncommonly occur on the scalp. Eyebrows, eyelashes, beard and body hair can be affected. Alopecia totalis describes complete loss of scalp hair, and alopecia universalis is complete loss of all hair. Nail pitting may occur. Spontaneous regrowth is usual for small patches of alopecia but the prognosis is less good for larger patches, more extensive involvement, early onset and an association with atopy.

Androgenetic alopecia

Male-pattern baldness is physiological in men over 20 years old, although it can also occur in adolescent. It is also found in women, particularly after the menopause. Characteristically, this involves bitemporal recession initially and subsequent involvement of the crown (‘male pattern’), although it is often diffuse in women.

Investigations

Important investigations include full blood count, renal and liver function tests, iron studies, thyroid function, autoantibody screen and syphilis serology, as several systemic diseases, particularly iron deficiency and hypothyroidism, can cause diffuse non-scarring alopecia. Hair pull tests may help to establish the ratio of anagen to telogen hairs but require expertise for interpretation. Scrapings and punchings should be sent for mycology if there is localised inflammation. Scalp biopsy and direct immunofluorescence of scarring alopecia may confirm a diagnosis of lichen planus or discoid lupus erythematosus but expert interpretation is needed.

**Hypertrichosis**

Hypertrichosis is a generalised or localised increase in hair and may be congenital or acquired. It can be primary or secondary; for example, to drugs such as ciclosporin, minoxidil or diazoxide, malignancy or eating disorders. Laser therapy or efflornithine, which inhibits ornithine decarboxylase and arrests hair growth while it is being used, may be helpful. When the hypertrichosis follows a male pattern, it is called hirsutism.

**Hirsutism**

Hirsutism is the growth of terminal hair in a male pattern in a female. The cause of most cases is unknown and, while it may occur in

hyperandrogenism, Cushing’s syndrome and polycystic ovary syndrome, only a small minority of patients have a demonstrable hormonal abnormality. Psychological distress is often significant and oral contraceptives containing an anti-androgen such as cyproterone acetate, laser therapy or topical efflornithine may be beneficial.

## Nail disorders

The nails can be affected by both local and systemic disease. The nail apparatus consists of the nail matrix and the nail plate, which arises from the matrix and lies on the nail bed (Fig. 27.45). The cells of the matrix and, to a lesser extent the bed, produce the keratinous plate.

Important information may be obtained from nail-fold examination, including dilated capillaries and ragged cuticles in connective tissue disease (Fig. 27.46) and the boggy inflammation of paronychia. The latter commonly occurs chronically in individuals undertaking wet work, in those with diabetes or poor peripheral circulation, and subsequent to increased cosmetic nail procedures and vigorous manicuring.

### Normal variants

Longitudinal ridging and beading of the nail plate occur with age. White transverse patches (striate leuconychia) are often caused by airspaces within the plate.

### Nail trauma

- **Nail biting/picking** is a very common habit. Repetitive proximal nail-fold trauma (often involving the thumb nail) results in transverse ridging and central furrowing of the nail.

![Fig. 27.45 The nail plate and bed. Arrows indicate the direction of nail growth.](image)

![Fig. 27.46 Dermatomyositis. Note the prominent periungual involvement. Erythema, dilated and tortuous capillaries in the proximal nail fold, and ragged cuticles are features of connective tissue disease.](image)
• Chronic trauma from poorly fitting shoes and sport can cause thickening and disordered growth of the nail (onychogryphosis) and subsequent ingrowing toenails.

• Splinter haemorrhages are fine, linear, dark brown longitudinal streaks in the plate (see Fig. 16.57). They are usually caused by trauma, especially if distal. Uncommonly, they can occur in nail psoriasis and are also a hallmark of infective endocarditis.

• Subungual haematoma is red, purple or grey–brown discoloration of the nail plate, usually of the big toe (Fig. 27.47). These haematomas are usually due to trauma, although a history of this may not be clear. The main differential is subungual melanoma, although rapid onset, lack of nail-fold involvement and proximal clearing as the nail grows are clues to the diagnosis of haematoma. If there is diagnostic doubt, a biopsy may be needed.

### Nail involvement in skin diseases

- **Dermatophyte infection/onychomycosis:** features are described earlier in the chapter in the section on skin infection.

- **Psoriasis:** nail involvement is common (see Fig. 27.36B).

- **Eczema:** nails may be shiny due to rubbing skin. Fine pitting can occur. If there is periungual eczema, the nail may become dystrophic, with thickening and transverse ridging. Paronychia is common.

- **Lichen planus:** there may be longitudinal ridging and thinning of the nail, giving a sandpaper texture (trachyonychia), erythematous streaks (erythronychia), subungual hyperkeratosis, pigmentation and, in severe cases, pterygium (splitting of nail due to central fibrosis and scarring, giving a winged appearance) and a destructive nail dystrophy.

- **Alopecia areata:** nail-plate pitting and trachyonychia can occur.

### Nail involvement in systemic disease

The nails may be affected in many systemic diseases and important examples are detailed below:

- **Beau's lines:** horizontal ridges/indentations in the nail plate occur simultaneously in all nails (Fig. 27.48B). They typically follow a systemic illness and are thought to be due to temporary growth arrest of cells in the nail matrix; they subsequently migrate out as the nail grows. Normal nail growth is approximately 0.1 mm/day for fingers and 0.05 mm/day for toes, so the timing of the systemic upset can usually be estimated by the position of the Beau's lines.

- **Koilonychia:** this concave or spoon-shaped nail-plate deformity is caused by iron deficiency (Fig. 27.48C).

- **Clubbing:** in the early stages, the angle between the proximal nail and nail fold is lost. In its more established form, there may be swelling of the distal digits (Figs. 27.48D and E) or toes. Causes include bronchogenic carcinoma, asbestosis (especially with mesothelioma), suppurative or fibrosing lung disease, cyanotic congenital heart disease, infective endocarditis, inflammatory bowel disease, biliary cirrhosis and thyrotoxicosis; rarely, clubbing can be familial or idiopathic.

- **Nail discoloration:** whitening may occur in hypoa1buminaemia. “Half-and-half” nails (white proximally and red/brown distally) may be found in renal failure. Antimalarials and some other drugs occasionally discolour nails.

### Nail involvement in congenital disease

Nails can be affected in congenital diseases, such as pachyonychia congenita, a rare, usually autosomal dominant, condition caused by mutations in differentiation-specific keratin genes 6A, 6B, 16 and 17. This results in palmoplantar keratoderma and gross nail discoloration and thickening, due to subungual hyperkeratosis, from birth.

### Skin disease in general medicine

Many skin conditions present to other medical specialties. These are listed in Box 27.32 and the most common ones that are not discussed elsewhere are detailed below.

### Conditions involving cutaneous vasculature

#### Vasculitis

Vasculitic involvement of the skin usually presents as palpable purpura (see Fig. 26.54). The diagnosis is confirmed by skin biopsy, along with histology and immunofluorescence examination. Vasculitis is discussed in more detail in Chapter 26.

#### Pyoderma gangrenosum

The initial lesion of pyoderma gangrenosum (PG) is usually a painful, tender, inflamed nodule or pustule, which breaks down centrally and rapidly progresses to an ulcer with an indurated, undermined purpurish or pustular edge (Fig. 27.49). Lesions may be single or multiple and are classified as ulcerative, pustular, bullous or vegetative. PG usually occurs in adults and, although it may occur in isolation, is usually associated with underlying disease, particularly inflammatory bowel disease, inflammatory arthritis, blood dyscrasias, immunodeficiences and HIV infection. Investigation should be made with these associations in mind. The diagnosis is largely clinical, as histology is not specific. Anaesthetics, treatment of secondary bacterial infection and supportive dressings are important. Systemic treatment with glucocorticoids, dapsone, ciclosporin or other immunosuppressants is often required. Predisolone and ciclosporin have been shown in a randomised controlled trial to be of similar efficacy and can thus both be considered in the management of pyoderma gangrenosum, allowing individual patient comorbidities and risk factors to be taken into account. Tetraacyclines may be added for their anti-inflammatory effects. There are reports of efficacy with TNF-α (infliximab, adalimumab), IL-12/23 (ustekinumab) and IL-17 (brodulimumab and secukinumab) inhibitors for severe recalcitrant PG, although as this is a rare orphan disease, evidence is relatively limited. Once healing has taken place, recurrences are typically only intermittent.

Skin problems in general medicine

Primary skin problems
- Cellulitis
- Vasculitis
- Pressure sores

Skin involvement in multisystem disease
- Genetic: neurofibromatosis, tuberous sclerosis
- Xanthomas
- Amyloidosis
- Non-specific and variable skin reactions to systemic disease
- Urticaria
- Erythema multiforme
- Erythema nodosum
- Pyoderma gangrenosum
- Sweet syndrome
- Generalised pruritus

Skin conditions associated with malignancy
- Dermatomyositis
- Acanthosis nigricans
- Generalised pruritus
- Superficial thrombophlebitis

Skin problems associated with specific medical disorders
- Liver: generalised pruritus, pigmentation, spider naevi
- Kidney: generalised pruritus, uraemic frost, pigmentation
- Diabetes mellitus: necrobiosis lipoidica, diabetic dermopathy
- Cutaneous Crohn’s disease

Skin problems secondary to treatment of systemic disease
- Drug eruptions

Miscellaneous
- Granuloma annulare
- Morphea

Pressure sores
Localised, prolonged, pressure-induced ischaemia can lead to the development of pressure sores, which can occur in up to 30% of hospitalised older adults. They are associated with considerable morbidity, mortality and expense to health services. The main risk factors are immobility, poor nutrition, local tissue hypoxia – for example, with anaemia, peripheral vascular disease, diabetes, sepsis and skin atrophy – or barrier impairment, such as in eczema.

A localised area of erythema develops at sites of bony prominences (particularly sacrum, greater trochanter, ischial and calcaneal tuberosities, and lateral malleolus). This progresses to a blister and then erosion, which will develop into a deep necrotic ulcer, usually colonised by Pseudomonas aeruginosa if pressure is not alleviated.

Prevention is key and involves identification of at-risk patients and regular repositioning and use of pressure-relieving mattresses. Predisposing factors, such as anaemia and poor nutrition, should be corrected. Once established, significant infection must be treated and necrotic tissue debrided. Dressings encourage granulation, although surgical intervention may sometimes be needed.

Connective tissue disease

Lupus erythematosus

This autoimmune disorder can be subdivided into systemic lupus erythematosus (SLE) and cutaneous lupus, which includes discoid lupus erythematosus (DLE) and subacute cutaneous lupus erythematosus (SCLE). The features of SLE are discussed in Chapter 26 (see Box 26.63, and Boxes 27.35 and 27.36 below). DLE typically presents as scaly red plaques with follicular plugging, usually on photo-exposed sites of the face, head and neck, which resolve with scarring and pigmentary change. If the scalp is involved, scarring alopecia usually occurs (Fig. 27.51). Most patients with DLE do not develop SLE. Patients with SLE may have extensive cutaneous involvement, usually aggravated by sun exposure, with an annular, polycyclic or papulosquamous eruption. Systemic involvement is uncommon and the prognosis usually good. There is a strong association with antibodies to Ro/SS-A antigen. A diagnosis of cutaneous lupus is confirmed by histopathology and direct immunofluorescence. Cutaneous lupus may respond to topical glucocorticoids, antimalarials or immunosuppressants. Antimalarials and photoprotection are important mainstays in the management of cutaneous lupus, and systemic immunosuppression may be required for resistant disease. Paradoxically, low-dose UV1A phototherapy can be effective for lupus.

Systemic sclerosis

This autoimmune multisystem disease presents with severe Raynaud’s syndrome, digital ulcers and skin fibrosis. Dilated nail-fold capillaries and ragged cuticles are frequent. The clinical features and management are described in Chapter 26.

Morphea

Morphea is a localised cutaneous form of scleroderma that can affect any site at any age. It usually presents as a thickened violaceous plaque, which may become hyper- or hypopigmented. Plaques can become generalised. Linear forms exist and, if in the scalp, are associated with scarring hair loss (en coup de sabre). There is usually no systemic involvement. Topical glucocorticoids or immunosuppressants or phototherapy, particularly PUVA or UVA1, can be effective, and systemic immunosuppression may be used for resistant extensive disease.

Dermatomyositis

Dermatomyositis is a multisystem disease, predominantly affecting skin, muscles and blood vessels. Typical cutaneous features include a violaceous “heliotrope” erythema periorbitally and involving the upper eyelids,
but this can sometimes affect the upper trunk, shoulders (‘shawl sign’) and limbs. Linear erythematous streaks may also be observed on the back of hands and fingers, and papules over the knuckles (Gottron’s papules). Tortuous dilated nail-fold capillaries, often best seen with a dermatoscope, and ragged cuticles are usually evident (Fig. 27.46). Photaggravation of the cutaneous features is often prominent (Fig. 27.50). The clinical features and management are described in Chapter 26.

**Granulomatous disease**

**Granuloma annulare**

This is common and may be reactive, although a trigger is usually not apparent. The hallmark is the presence of dermal granulomas, which are usually palisading and associated with alteration of dermal collagen (necrobiosis). The condition is generally asymptomatic and may present as an isolated dermal lesion with a raised papular annular edge, or may be more generalised. An association between generalised disease and diabetes has been proposed but not confirmed. Lesions often resolve spontaneously. Intraliesional glucocorticoids or cryotherapy can be used for localised disease, and UVB or UVA1 phototherapy or PUVA for generalised disease.

**Necrobiosis lipoidica**

This condition has some histological features in common with granuloma annulare, although necrobiosis predominates. The lesion has a characteristic yellow, waxy, atrophic appearance, often with violaceous edge (Fig. 27.52). Underlying blood vessels are easily seen because of tissue atrophy. Necrobiosis lipoidica typically appears on the shins and is prone to ulceration after trauma. There is a strong association with diabetes: most patients with necrobiosis lipoidica have or develop diabetes, although less than 1% of diabetic patients develop necrobiosis lipoidica. Treatment is difficult and includes very potent topical or intraliesional glucocorticoids, topical calcineurin inhibitors, PUVA or UVA1 phototherapy and systemic immunosuppression.

**Sarcoidosis**

This condition is characterised by the presence of non-caseating granulomas. The cause is unknown, although infectious and genetic factors have been proposed. It is usually a multisystem disease, with skin lesions in about one-third of patients. Cutaneous features can occur in isolation and include violaceous infiltrated dermal plaques and nodules, which can affect any site but particularly digits and nose (lupus pernio), more generalised hyper- or hypopigmented or annular papules and plaques, infiltrative changes in scars and erythema nodosum (see Fig. 17.57). It has been reported more commonly and may be more severe in those of African, African American or South Asian ancestry. Cutaneous disease may respond to topical or intraliesional glucocorticoids, cryotherapy, UVA1, laser or PDT. Clinical features, investigation and management of systemic disease are discussed in Chapter 17.

**Cutaneous Crohn’s disease**

Cutaneous Crohn’s disease is rare but may present as perianal and peristomal infiltrative plaques, lymphoedema, sinuses or fistulae, and oral granulomatous disease. These changes are termed ‘metastatic’ Crohn’s and histology shows non-caseating granulomas. Reactive skin changes can also occur in the form of erythema nodosum and pyoderma gangrenosum. Treatment is of the underlying disease.

**Porphyrias**

The porphyrias are a diverse group of diseases, caused by reduced or absent activity of specific enzymes in the porphyrin–haem biosynthetic pathway. Due to this loss of enzyme activity, porphyrin precursors proximal to the implicated enzyme step accumulate. If the accumulated porphyrins absorb visible light, then there will be skin features and photosensitivity, which explains why some porphyrias have skin features (porphyria cutanea tarda) and others do not (acute intermittent porphyria). The most common skin presentations are photo-exposed site blistering, skin fragility and pain on daylight exposure.

---

**Fig. 27.50** Dermatomyositis. Photo-aggravation in dermatomyositis.

**Fig. 27.51** Scarring inflammatory alopecia. This patient had systemic lupus erythematosus and additional cutaneous features of scarring inflammatory discoid lupus erythematosus.

**Fig. 27.52** Necrobiosis lipoidica. Atrophic yellow plaques with violaceous edges, on the shins of a patient with diabetes mellitus.
**Cutaneous porphyrias: fragility and blisters**

Although porphyria cutanea tarda (PCT) may be genetically inherited, this is uncommon and acquired PCT is the most common porphyria worldwide. It is caused by an underlying chronic liver disease, in association with hepatic iron overload. The liver disease is often only diagnosed through investigation of the skin presentation and it is thus an important diagnosis not to miss. Typical features are increased skin fragility, blistering, erosions, hypertrichosis, scarring and milia occurring on light-exposed areas, particularly the backs of the hands (Fig. 27.53). Less common features include facial hypertrichosis, hyperpigmentation and morphea-like changes. Variegate porphyria (VP) and hereditary coproporphyria (HCP) may be indistinguishable on skin features and it is important to make the correct diagnosis, as acute neurovisceral attacks, which may be drug-induced, can occur in VP and HCP but not in PCT. Pseudoporphyrina may also be impossible to distinguish from PCT on clinical grounds but is most frequently caused by a drug (commonly naproxen); see Box 27.36) or by sunbed use; on investigation, porphyrins are normal. A PCT-like presentation may also be seen in uraemia due to renal failure, but is caused by raised porphyrins due to impaired elimination rather than an enzyme defect.

Management of PCT requires removal or treatment of any underlying cause, which may involve venesection, iron chelation, very low-dose hydroxychloroquine once or twice per week and photoprotection.

**Cutaneous porphyria: pain on sun exposure**

Erythropoietic protoporphyria is caused by a genetic defect in the ferrochelatase gene that leads to ferrochelatase enzyme deficiency. It is an important diagnosis to consider. The presentation is usually in early childhood, although the diagnosis is often delayed. In part this is because, although the baby or child cries due to immediate pain on sunlight exposure, physical signs are often absent or minimal and thus a link with sunlight may not always be considered. The deficient ferrochelatase activity leads to accumulation of lipid-soluble protoporphyria in the skin, explaining the photosensitivity manifest as pain on daylight exposure. Multiple pigment gallstones, anaemia (usually only problematic if considered to be due to iron deficiency) and, rarely, severe liver disease can occur, which may be fatal and requires liver transplantation. In addition to photoprotection, UVB phototherapy may be effective for the symptoms of photosensitivity and, more recently, the use of alpha-melanocyte-stimulating hormone (α-MSH) analogues has been explored.

**Abnormal deposition disorders**

**Xanthomas**

Deposits of fatty material in the skin, subcutaneous fat and tendons may be the first clue to primary or secondary hyperlipidaemia.

**Amyloidosis**

Cutaneous amyloid may present as periocular plaques in primary systemic amyloidosis and amyloid associated with multiple myeloma, but is uncommon in systemic amyloidosis secondary to rheumatoid arthritis or other chronic inflammatory diseases. Amyloid infiltration of blood vessels may manifest as ‘pinch purpura’ following skin trauma. Macular amyloid is more common in darker skin types and appears as purplish grey/brown macules or patches, usually on the back. Potent topical glucocorticoids can be beneficial, although it is often treatment-resistant.

**Genetic disorders**

**Neurofibromatosis**

This condition can present with skin lesions. More details are provided in Chapter 28.

**Tuberous sclerosis**

This is an autosomal dominant condition and two genetic loci have been identified: TSC1 (chromosome 9 encoding hamartin, and TSC2 (chromosome 16) encoding tuberin. The hallmark is hamartomas in many systems. The classic triad of clinical features comprises learning disability, epilepsy and skin lesions but there is marked heterogeneity in clinical features. Skin changes include pale oval (ash leaf) macules that occur in early childhood; yellowish/pink papules in the mid-face (angiofibromas, ‘adenoma sebaeum’), occurring in adolescence; periungual and subungual fibromas; and connective tissue naevi (shagreen patches, often on lower back). Curn hyperplasia, retinal phakomas (fibrous overgrowths), renal, lung and heart tumours, cerebral gliomas and calcified basal ganglia may also occur.

**Reactive disorders**

**Erythema multiforme**

Erythema multiforme has characteristic clinical and histological features and can be triggered by a variety of factors (Box 27.33) but a cause is not always identified. The disease is likely to have an immunological basis. Lesions are multiple, erythematous, annular, targetoid ‘bull’s eyes’ (Fig. 27.54) and may blisters. Stevens–Johnson syndrome is a severe form of erythema multiforme with marked blistering, mucosal involvement (mouth, eyes and genitals) and systemic upset.

Identification and removal/treatment of any trigger are essential. Analgesia and topical glucocorticoids may provide symptomatic relief. Supportive care is required in Stevens–Johnson syndrome, including ophthalmology input.

**Erythema nodosum**

This is characterised histologically by a septal panniculitis of subcutaneous fat (see Fig. 17.59). An identified trigger is often present.
Lesions are typically painful, indurated violaceous nodules on the shins and lower legs. Systemic upset, arthralgias and fever are common. Spontaneous resolution occurs over a month or so, leaving bruise-like marks. Any underlying cause should be identified and removed or treated. Bed rest, leg elevation and an oral NSAID frequently offer symptomatic relief. Systemic glucocorticoids are effective but seldom required, and must be avoided when there is a possibility of infection. Potassium iodide, dapsone or hydroxychloroquine may be effective for resistant disease but these are rarely required.

## Acquired reactive perforating dermatosis

The hallmark of this condition is transepidermal elimination of dermal material, particularly collagen and tissue. It presents as keratotic papules, particularly in patients with diabetes and chronic renal disease. Treatment with topical glucocorticoids, retinoids, PUVA or UVA1 therapy may help. There are other related perforating dermatopaties, with characteristic histology.

## Annular erythemas

This group of chronic, poorly defined, annular, erythematous and often scaly eruptions can be further subdivided and may be secondary to an identifiable cause. Erythema chronicum migrans can be associated with Lyme disease (Borrelia burgdorferi). Erythema marginatum can occur in rheumatic fever or Still’s disease. Erythema gyratum repens typically presents as concentric circles of erythema and scale with an advancing edge and is usually associated with underlying malignancy. Erythema annulare centrifugum presents with expanding, scaly, erythematous rings, with central fading. A trigger may not be apparent but possible associations include fungal infection, drugs, autoimmune or endocrine diseases, such as lupus or thyroid disease, and malignancy, particularly haematological. An underlying trigger must be sought and removed or treated. Topical glucocorticoids or phototherapy may be helpful for chronic disease.

## Acanthosis nigricans

Hyperkeratosis and pigmentation are typical and affected sites have a velvety texture. The flexures, especially axillae and, in dark-skinned people, sides of neck, are involved. There are several types, mainly associated with insulin resistance. Most often, acanthosis nigricans is found in conjunction with obesity and regresses with weight loss. It can be associated with malignancy, usually adenocarcinoma (particularly gastric), when it is usually more extensive and pruritic, and can involve mucous membranes.

### Drug eruptions

Virtually all drugs may have cutaneous adverse effects (Fig. 27.55) and this should be considered in the differential diagnosis of most presentations of skin disease. Drugs can exert their adverse effects via several mechanisms, which can be broadly subdivided into non-immunological and immunological (Box 27.35).

(ACE = angiotensin-converting enzyme; AGEP = acute generalised exanthematous pustulosis; DRESS = drug rash with eosinophilia and systemic symptoms; EGFR = epidermal growth factor receptor; NSAIDs = non-steroidal anti-inflammatory drugs; PAS = para-aminosalicylic acid; TNF = tumour necrosis factor)
Clinical features

Cutaneous drug reactions typically present in specific patterns (Box 27.36). Non-immunologically mediated reactions can theoretically occur in anyone, given sufficient exposure to the drug, although idiosyncratic factors, such as genetic predisposition, may render some more susceptible. There is limited information on genetic determinants of drug responses and adverse effects, although advances have been made providing opportunities for personalised medicine. Immunologically mediated cutaneous drug eruptions typically commence within days to weeks of starting the drug. Detailed history-taking relating to prescribed and non-prescribed medications is essential and there may be other clues (Box 27.37).

Investigations and management

The suspected drug must be stopped. If drug-induced photosensitivity is considered, the patient should be phototested while on the drug to confirm the diagnosis, and again after drug withdrawal to confirm resolution of photosensitivity. An eosinophilia and abnormalities in liver function tests may occur in adverse drug reactions and, for example, specific IgE to penicillin may be raised in penicillin-induced rash but, otherwise, specific investigations are not available. Rechallenge with drug is not usually undertaken unless the reaction is mild, as this can be risky. Drug withdrawal may not be straightforward and substitute drugs may be required. Antihistamines and/or topical or systemic glucocorticoids may provide supportive management, depending on the type of cutaneous reaction. The management of anaphylaxis is described in Chapter 9.

27.1. A 29-year-old woman with type 1 diabetes mellitus and Crohn’s disease presented with an 8-week history of a painful enlarging ulcer on her shin. It had started as a tender lump, which she thought developed after an insect bite. She was otherwise well, with no fever, although reported fatigue and malaise in recent weeks. Examination revealed a large superficial ulcer on the shin, with a raised violaceous edge (see Figure). What is the most likely diagnosis?

A. Erythema nodosum
B. Necrobiosis lipoidica
C. Cutaneous Crohn’s disease
D. Necrotising fasciitis
E. Pyoderma gangrenosum

Answer: E.

Pyoderma gangrenosum is an uncommon neutrophilic dermatosis, which may occur in association with a range of diseases, including inflammatory bowel disease. It typically presents as a tender purple nodule, which rapidly breaks down and ulcerates and may heal with cribriform scarring. Immunosuppression may be needed until healed, although it generally does not recur. Erythema nodosum typically presents as tender nodules on shins, although can occur at any site. It is a reactive skin presentation and triggers include streptococcal infection, inflammatory bowel disease, rheumatoid arthritis, sarcoid and drugs. Lesions are often multiple and do not usually rapidly increase in size or ulcerate. Necrobiosis lipoidica is strongly associated with type 1 diabetes mellitus and typically presents as atrophic enlarging yellow-coloured plaques on the shins, which may ulcerate. A raised violaceous edge would be most unusual as atrophy is the hallmark. Cutaneous Crohn’s is rare and usually involves perineal or peristomal sites, presenting with infiltrative plaques, sinuses and fistulae. Necrotising fasciitis is rare and must be recognised and managed urgently as it is life-threatening. Patients are usually acutely unwell, febrile and in pain and rapidly evolving skin and deep soft tissue necrosis occurs, with crepitus evident on palpation. Bacterial cultures are positive and patients must be urgently managed through multidisciplinary supportive care, intravenous antibiotics and surgical débridement of necrotic tissue.

27.2. A 35-year-old woman with persistent severe acne vulgaris was referred for consideration of isotretinoin therapy. She had a history of anxiety and had not yet completed her family, so was concerned about possible side-effects. She had gathered information from friends and researching the internet, but was not sure if this was accurate. She arrived in clinic with a list of questions and hoped that her doctor could reassure her. Which of the following statements about isotretinoin therapy is true?

A. High cholesterol levels are a common side-effect
B. Conception should be avoided until 2 weeks after the treatment course
C. Mood disturbance during treatment occurs in most people
D. Dryness of lips and eyes is related to drug dose
E. Easy sunburning can persist for years after treatment

Answer: D.

Dryness of eyes and mouth is a common side-effect of isotretinoin through non-immunological dose-dependent direct toxicity. Isotretinoin commonly causes transient rise in triglycerides during treatment, but cholesterol is not usually significantly elevated. Conception must be avoided for at least one month after isotretinoin is discontinued as it is highly teratogenic and slowly eliminated. A range of mood disturbances has been reported in association with isotretinoin therapy, including an unproven risk of suicide. However, whilst mood monitoring during treatment is important, most patients do not experience lowering of mood and many find that their mood improves as their acne resolves. Isotretinoin can increase light sensitivity, even to wintertime or window glass-transmitted light. However, once the drug is stopped, light sensitivity will resolve and there is no evidence that it can persist long term.

27.3. A 22-year-old man presented with a 6-month history of a rash on his elbows, knees, shoulders and buttocks, which he described as being so itchy that he had not slept for months. He was otherwise well and on no medications, other than isotretinoin tablets. On examination there were excoriations at the affected sites but no other specific signs. A skin biopsy was taken from an affected area. What would you expect to see on H&E staining and direct immunofluorescence?

A. Sub-epidermal vesicles and granular IgA in the papillary dermis
B. Sub-epidermal vesicles and linear IgG at basement membrane
C. Intra-epidermal vesicles and granular IgA in the papillary dermis
D. Intra-epidermal vesicles and linear IgG at basement membrane
E. Sub-epidermal vesicles and linear IgA in the papillary dermis

Answer: A.

Sub-epidermal vesicles and granular IgA in the papillary dermis would be expected observations on skin biopsy analysis as the history and examination findings are highly suggestive of dermatitis herpetiformis and coeliac disease. The affected body sites and intense itch are typical and intact vesicles and blisters are not usually visible as they are de-roofed through scratching, with only excoriation remaining. Iron deficiency in an otherwise well 22-year-old male is unusual and strongly suggests malabsorption. Typical biopsy findings of lesional skin are of sub-epidermal vesicles in the dermal papillae, with a neutrophilic and eosinophilic infiltrate. Direct immunofluorescence shows granular IgA in the papillary dermis. The immunofluorescence findings can also be detected in the non-affected skin of the patient. Other investigations that can be performed include tissue transglutaminase and anti-endomysial antibodies, although characteristic biopsy findings are diagnostic. If the diagnosis of
coeliac disease is uncertain, jejunal biopsy may be indicated. Dermatitis herpetiformis usually responds well to a gluten-free diet, with dapsone also being needed in some cases.

27.4. A 44-year-old woman attended the local dermatology clinic with a 2 month history of an itchy erythematous, scaly rash on her eyelids. She had no rash elsewhere and was fit and well, although she had a history of atopic dermatitis as a child. She was on no medication and worked as a nail technician at a beauty salon. On examination there were bilateral eczematous changes on both upper eyelids but no other abnormal signs. Allergic contact dermatitis was suspected. Patch testing was performed and showed a strong positive allergic reaction to a relevant allergen. Which of the following allergens is the most likely culprit?

A. Wool alcohol
B. Colophony
C. Paraphenylenediamine
D. Parabens
E. Dichromate

Answer: B.

Colophony is the likely allergen. It is present in sticking plasters, colloidions and varnishes, and eyelid eczema can be an isolated manifestation of allergic contact dermatitis to colophony due to rubbing and touching eyelids. All of the provided answers are common allergens but the clues in this case are that she only had the eczematous rash on her eyelids and not elsewhere and that she worked as a nail technician.

27.5. A 38-year-old woman contacted her doctor as she wanted to get more information on how best to protect her 6-month old baby from the sun as they were planning a sunny holiday. The doctor advised her about shade, hats and clothing and gave specific advice about sunscreens. Which of the following statements is true?

A. Sunblocks provide more sun protection than sunscreens
B. Sunscreens offer only 50%–60% of the sun protection factor (SPF) stated on the bottle
C. Reflectant sunscreens offer superior protection in the longer UVR wavelengths
D. Sunscreens should be avoided in babies as they commonly cause allergy
E. Sunscreen patch testing is the investigation of choice if allergy is suspected

Answer: C.

Reflectant sunscreen chemicals provide better protection against the longer UVA wavelengths than absorbent sunscreen chemicals. There is no such thing as a sunblock – all sunscreens offer partial protection at best. Studies have shown that with real-life sunscreen use, only 25%–33% of the stated sun protection factor (SPF) on the product is achieved. Sun protection for babies should mainly be through avoidance, shade and covering up, with sunscreens for unavoidable exposure at limited sites. However, sunscreens do not commonly cause allergy – if sunscreen reactions do occur they are usually due to irritancy, not allergy, with only the minority of reactions being true allergy or photoallergy. The investigation of choice for suspected sunscreen allergy is photopatch testing as photoallergic reactions may be missed on standard patch testing.

### Motor and sensory homunculi

The motor and sensory homunculi illustrate the cortical areas serving each anatomical area within the pre-central (motor) and post-central (sensory) gyri.
The complexity of the brain differentiates us from other species, and its interactions with the spinal cord and peripheral nerves combine to allow us to perceive and react to the external world while maintaining a stable internal environment. The cerebral cortex provides a platform for processing information and forming a response, and in doing so, both forms and is affected by our personality and mental state.

Neurology has for too long been misperceived as a specialty in which intricate clinical examination and numerous investigations are required to diagnose obscure and untreatable conditions. In fact, nervous system disorders are common, accounting for 10% of the UK’s general practice consultations, 20% of acute medical admissions and most chronic physical disability. The development of specific, effective treatments has made accurate diagnosis essential. Neurological management requires knowledge of a range of common conditions, which can be applied to individual patients after careful history-taking, with lesser contributions arising from targeted examination and considered investigation.

Pathological and anatomical localisation of symptoms and signs is important, but skill can be required to identify those not associated with neurological disease, differentiating patients requiring investigation and treatment from those who need reassurance.

Initially, it is important to exclude conditions that constitute neurological emergencies (Box 28.1). If the presentation is not an emergency, time can be taken to reach a diagnosis. The history should provide a hypothesis for the site and nature of the potential pathology, which a focused examination may refine, and direct appropriate further investigations. An informed discussion with the patient and family regarding diagnosis, management and prognosis may then take place.

As stroke has become a specific subspecialty in many centres, it is described in Chapter 29. This chapter should be read with it, to help clarify how the presentation, diagnosis and management of stroke present their own challenges.

### Functional anatomy and physiology

#### Cells of the nervous system

The nervous system comprises billions of specialised cells, forming a spectacular network of connections. In addition to neurons, there are many types of glial cells. Astrocytes form the structural framework for neurons and control their biochemical environment, their foot processes adjoining small blood vessels and forming the blood–brain barrier (Fig. 28.1). Oligodendrocytes are responsible for the formation and maintenance of the myelin sheath, which surrounds axons and is essential for maintaining the speed and consistency of action potential propagation along axons. Peripheral nerves have axons invested in myelin made by oligodendrocytes (Schwann cells). Microglial cells derive

from monocytes/macrophages and play a role in fighting infection and removing damaged cells. Ependymal cells line the cerebral ventricles.

## Generation and transmission of the nervous impulse

The role of the central nervous system (CNS) is to generate outputs in response to external stimuli and changes in internal conditions. The CNS has to maintain a delicate balance between responsivity to external stimuli and remaining stoic enough to remain stable in a rapidly changing environment. Each neuron receives input by synaptic transmission from dendrites (branched projections of other neurons), which sum to produce output in the form of an action potential that is then conducted along the axon, resulting in synaptic transmission to other neurons or, in the motor system, to muscle cells. Summation of the inputs causes net changes in the target neuron’s electrophysical gradient, which, if large enough, will trigger an action potential. Communication between cells is by synaptic transmission that involves the release of neurotransmitters to interact with structures on the target cell’s surface, including ion channels and other receptors (Fig. 28.2).

At least 20 different neurotransmitters act at different sites in the nervous system, most of which are potentially amenable to pharmacological manipulation.

Each neuronal cell body may receive synaptic input from thousands of other neurons. The synapsing neuron terminals are also subject to feedback regulation via receptor sites on the pre-synaptic membrane, modifying the release of transmitter across the synaptic cleft. In addition to such acute effects, some neurotransmitters produce long-term modulation of metabolic function or gene expression. This effect probably underlies more complex processes such as long-term memory.

### Functional anatomy of the nervous system

Major components of the nervous system and their inter-relationships are depicted in Figure 28.3.

### Cerebral hemispheres

The cerebral hemispheres coordinate the highest level of nervous function, the anterior half dealing with executive (‘doing’) functions and the posterior half constructing a perception of the environment. Each cerebral hemisphere has four functionally specialised lobes (Box 28.2 and Fig. 28.4), with some functions being distributed asymmetrically (“lateralised”), to produce cerebral dominance for functions such as motor control, speech or memory. Cerebral dominance aligns limb dominance with language function; in right-handed individuals the left hemisphere is almost always dominant, while around half of left-handers have a dominant right hemisphere.

Frontal lobes are concerned with executive function, movement, behaviour and planning. As well as the primary and supplementary motor cortex, there are specialised areas for control of eye movements, speech (Broca’s area) and micturition.

---

**Fig. 28.2** Neurotransmission and neurotransmitters. (1) An action potential arising at the nerve terminal depolarises the membrane and this opens voltage-gated calcium channels. (2) Entry of calcium causes the fusion of synaptic vesicles containing neurotransmitters with the pre-synaptic membrane and release of the neurotransmitter across the synaptic cleft. (3) The neurotransmitter binds to receptors on the post-synaptic membrane either (A) to open ligand-gated ion channels that, by allowing ion entry, depolarise the membrane and initiate an action potential (4), or (B) to bind to metabotropic receptors that activate an effector enzyme (e.g. adenylyl cyclase) and thus modulate gene transcription via the intracellular second messenger system, leading to changes in synthesis of ion channels or modulating enzymes. (5) Neurotransmitters are taken up at the pre-synaptic membrane and/or metabolised. (cAMP = cyclic adenosine monophosphate; DNA = deoxyribonucleic acid; mRNA = messenger ribonucleic acid)

**Fig. 28.3** The major anatomical components of the nervous system.
The parietal lobes integrate sensory perception. The primary sensory cortex lies in the post-central gyrus of the parietal lobe. Much of the remainder is devoted to ‘association’ cortex, which processes and interprets input from the various sensory modalities. The supramarginal and angular gyri of the dominant parietal lobe form part of the language area (p. 1144). Close to these are regions dealing with numerical function. The non-dominant parietal lobe is concerned with spatial awareness and orientation.

The temporal lobes contain the primary auditory cortex and primary vestibular cortex. On the inner medial sides lie the olfactory and parahippocampal cortices, which are involved in memory function. The temporal lobes also link intimately to the limbic system, including the hippocampus and the amygdala, which are involved in memory and emotional processing. The dominant temporal lobe also participates in language functions, particularly verbal comprehension (Wernicke’s area). Musical processing occurs across both temporal lobes, rhythm on the dominant side and melody/pitch on the non-dominant.

The occipital lobes are responsible for visual interpretation. The contralateral visual hemifield is represented in each primary visual cortex, with surrounding areas processing specific visual submodalities such as colour, movement or depth, and the analysis of more complex visual patterns such as faces.

Deep to the grey matter in the cortices, and the white matter (composed of neuronal axons), are collections of cells known as the basal ganglia that are concerned with motor control; the thalamus, which is responsible for the level of attention to sensory perception; the limbic system, concerned with emotion and memory; and the hypothalamus, responsible for homeostasis, such as temperature and appetite control. The cerebral ventricles contain cerebrospinal fluid (CSF), which cushions the brain during cranial movement.

CSF is formed in the lateral ventricles and protects and nourishes the CNS. CSF flows from third to fourth ventricles and through foramina in the brainstem to dissipate over the surface of the CNS, eventually being reabsorbed into the cerebral venous system (see Fig. 28.42).

### The brainstem

In addition to containing all the sensory and motor pathways entering and leaving the hemispheres, the brainstem houses the nuclei and projections of most cranial nerves, as well as other important collections of neurons in the reticular formation (Fig. 28.5). Cranial nerve nuclei provide motor control to muscles of the head (including face and eyes) and coordinate sensory input from the special sense organs and the face, nose, mouth, larynx and pharynx. They also relay autonomic messages, including pupillary, salivary and lacrimal functions. The reticular formation is mainly involved in control of conjugate eye movements, the maintenance of balance and arousal, and cardiorespiratory control.

Inability to recognise familiar objects, e.g. faces.
Fig. 28.4 Anatomy of the cerebral cortex.

Fig. 28.5 Anatomy of the brainstem.

The spinal cord

The spinal cord is the route for virtually all communication between the extracranial structures and the CNS. Afferent and efferent fibres are grouped in discrete bundles but collections of cells in the grey matter are responsible for lower-order motor reflexes and the primary processing of sensory information.

Sensory peripheral nervous system

The sensory cell bodies of peripheral nerves are situated just outside the spinal cord, in the dorsal root ganglia in the spinal exit foramina, while the distal ends of their neurones utilise various specialised endings for the conversion of external stimuli into action potentials. Sensory nerves consist of a combination of large, fast, myelinated axons (which carry information about joint position sense and commands to muscles) and smaller, slower, unmyelinated axons (which carry information about pain and temperature, as well as autonomic function).

Motor peripheral nervous system

The anterior horns of the spinal cord comprise cell bodies of the lower motor neurons. To increase conduction speed, peripheral motor nerve axons are wrapped in myelin produced by Schwann cells. Motor neurones release acetylcholine across the neuromuscular junction, which changes the muscle end-plate potential and initiates muscle contraction.
The autonomic system

The autonomic system regulates the cardiovascular and respiratory systems, the smooth muscle of the gastrointestinal tract, and many exocrine and endocrine glands throughout the body. The autonomic system is controlled centrally by diffuse modulatory systems in the brainstem, limbic system, hypothalamus and frontal lobes, which are concerned with arousal and background behavioural responses to threat. Autonomic output divides functionally and pharmacologically into two divisions: the parasympathetic and sympathetic systems.

The motor system

A programme of movement formulated by the pre-motor cortex is converted into a series of excitatory and inhibitory signals in the motor cortex that are transmitted to the spinal cord in the pyramidal tract (Fig. 28.6). This passes through the internal capsule and the ventral brainstem before crossing (deussed) in the medulla to enter the lateral columns of the spinal cord. The pyramidal tract ‘upper motor neurons’ synapse with the anterior horn cells of the spinal cord grey matter, which form the lower motor neurons.

Any movement necessitates changes in posture and muscle tone, sometimes in quite separate muscle groups to those involved in the actual movement. The motor system consists of a hierarchy of controls that maintain body posture and muscle tone, on which any movement is superimposed. In the grey matter of the spinal cord, the lowest order of the motor hierarchy controls reflex responses to stretch. Muscle spindles sense lengthening of the muscle; they provide the afferent side of the stretch reflex and initiate a monosynaptic reflex leading to protective or reactive muscle contraction. Inputs from the brainstem are largely inhibitory. Polysynaptic connections in the spinal cord grey matter control more complex reflex actions of flexion and extension of the limbs that form the basic building blocks of coordinated actions, but complete control requires input from the extrapyramidal system and the cerebellum.

Lower motor neurons

Lower motor neurons in the anterior horn of the spinal cord innervate a group of muscle fibres termed a ‘motor unit’. Loss of lower motor neurons causes loss of contraction within this unit, resulting in weakness and reduced muscle tone. Subsequently, denervated muscle fibres atrophy, causing muscle wasting, and depolarise spontaneously, causing ‘fibrillations’. Except in the tongue, these are usually perceptible only on electromyography (EMG; p. 1132). With the passage of time, neighbouring intact neurons sprout to provide re-innervation, but the neuromuscular junctions of the enlarged motor units are unstable and depolarise spontaneously, causing fasciculations (large enough to be visible). Fasciculations therefore imply chronic denervation with partial re-innervation.

Upper motor neurons

Upper motor neurons have both inhibitory and excitatory influence on the function of lower motor neurons in the anterior horn. Lesions affecting the upper motor neuron result in increased tone, most evident in the strongest muscle groups (i.e. the extensors of the lower limbs and the flexors of the upper limbs). The weakness of upper motor neuron lesions is conversely more pronounced in the opposing muscle groups. Loss of inhibition will also lead to brisk reflexes and enhanced reflex patterns of movement, such as flexion withdrawal to noxious stimuli and spasms of extension. The increased tone is more apparent during rapid stretching (‘spastic catch’) but may quickly give way with sustained tension (the ‘clasp-knife’ phenomenon). More primitive reflexes are also released, manifest as extensor plantar responses. Spasticity may not be present until some weeks after the onset of an upper motor neuron lesion.

The extrapyramidal system

Circuits between the basal ganglia and the motor cortex constitute the extrapyramidal system, which controls muscle tone, body posture and the initiation of movement (see Fig. 28.6). Lesions of the extrapyramidal system produce an increase in tone that, unlike spasticity, is continuous throughout the range of movement at any speed of stretch (‘lead pipe’ rigidity). Involuntary movements are also a feature of extrapyramidal lesions, and tremor in combination with rigidity produces typical ‘cogwheel’ rigidity. Extrapyramidal lesions also cause slowed and clumsy movements (bradykinesia), which characteristically reduce in size with repetition, as well as postural instability, which can precipitate falls.

The cerebellum

The cerebellum fine-tunes and coordinates movement initiated by the motor cortex, including articulation of speech. It also participates in the planning and learning of skilled movements through reciprocal connections with the thalamus and cortex. A lesion in a cerebellar hemisphere causes lack of coordination on the same side of the body. Cerebellar dysfunction impairs the smoothness of eye movements, causing nystagmus, and renders speech dysarthric. In the limbs, the initial movement is normal, but as the target is approached, the accuracy of the movement deteriorates, producing an ‘intention tremor’. The distances of targets are misjudged (dysmetria), resulting in ‘past-pointing’. The ability to produce rapid, accurate, regularly alternating movements is also impaired (dysdiadochokinesis). The central vermis of the cerebellum is concerned with the coordination of gait and posture. Disorders of this area therefore produce a characteristic ataxic gait (see below).
**Fig. 28.7** Visual pathways and visual field defects. Schematic representation of eyes and brain in transverse section.

**Fig. 28.8** Control of conjugate eye movements. Downward projections pass from the cortex to the pontine lateral gaze centre (A). The pontine gaze centre projects to the 6th cranial nerve nucleus (B), which innervates the ipsilateral lateral rectus and projects to the contralateral 3rd nerve nucleus (and hence medial rectus) via the medial longitudinal fasciculus (MLF). Tonic inputs from the vestibular apparatus (C) project to the contralateral 6th nerve nucleus via the vestibular nuclei.

**Fig. 28.9** Areas of the cerebral cortex involved in the generation of spoken language.

Normally, the eyes move conjugately (in the same direction at the same speed), though horizontal convergence allows fusion of images at different distances. The control of eye movements begins in the cerebral hemispheres, particularly within the frontal eye fields, and the pathway then descends to the brainstem with input from the visual cortex, superior colliculus and cerebellum. Horizontal and vertical gaze centres in the pons and mid-brain, respectively, coordinate output to the ocular motor nerve nuclei (3, 4 and 6), which are connected to each other by the medial longitudinal fasciculus (MLF) (Fig. 28.8). The MLF is particularly important in coordinating horizontal movements of the eyes. The resulting signals to extraocular muscles are supplied by the oculomotor (3rd), trochlear (4th) and abducens (6th) cranial nerves.

The pupillary size is determined by a combination of parasympathetic and sympathetic activity. Parasympathetic fibres originate in the Edinger–Westphal subnucleus of the 3rd nerve, and pass with the 3rd...
nerve to synapse in the ciliary ganglion before supplying the constrictor pupillae of the iris. Sympathetic fibres originate in the hypothalamus, pass down the brainstem and cervical spinal cord to emerge at T1, return up to the eye in association with the internal carotid artery, and supply the dilator pupillae.

**Speech**

Much of the cerebral cortex is involved in the process of forming and interpreting communicating sounds, especially in the dominant hemisphere (see Box 28.2). Decoding of speech sounds (phonemes) is carried out in the upper part of the posterior temporal lobe. The attribution of meaning, as well as the formulation of the language required for the expression of ideas and concepts, occurs predominantly in the lower parts of the anterior parietal lobe (the angular and supramarginal gyri). The temporal speech comprehension region is called Wernicke’s area (Fig. 28.9). Other parts of the temporal lobe contribute to verbal memory, where lexicons of meaningful words are “stored”. Parts of the non-dominant parietal lobe appear to contribute to non-verbal aspects of language in recognising meaningful intonation patterns (prosody).

The frontal language area is in the posterior end of the dominant inferior frontal gyrus known as Broca’s area. This receives input from the temporal and parietal lobes via the arcuate fasciculus. The motor commands generated in Broca’s area pass to the cranial nerve nuclei in the pons and medulla, as well as to the anterior horn cells in the spinal cord. Nerve impulses to the lips, tongue, palate, pharynx, larynx and respiratory muscles result in the series of ordered sounds comprising speech. The cerebellum also plays an important role in coordinating speech, and lesions of the cerebellum lead to dysarthria, where the problem lies in motor articulation of speech.

**Fig. 28.10** The areas supplied by specific levels of the spinal cord. These are approximations and in practice there is much overlap. The clinical utility of these dermatomes has diminished somewhat with the advent of good magnetic resonance imaging of the spinal cord but it remains important to ascertain the presence of a ‘spinal level’ of sensation, to remember the supply of the saddle area, and to note the cervical descent of some spinal spinothalamic pathways. A Anterior. B Posterior.

**Fig. 28.11** The main somatic sensory pathways.
The somatosensory system

The body surface can be described by dermatomes, each dermatome being an area of skin in which sensory nerves derive from a single spinal nerve root (Fig. 28.10). Sensory information ascends in two anatomically discrete systems (Fig. 28.11). Fibres from proprioceptive organs and those mediating specific sensation (including vibration) enter the spinal cord at the posterior horn and pass without synapsing into the ipsilateral posterior columns. In contrast, fibres conveying pain and temperature sensory information (nociceptive neurons) synapse with second-order neurons that cross the midline in the spinal cord before ascending in the contralateral anterolateral spinothalamic tract to the brainstem.

The second-order neurons of the dorsal column sensory system cross the midline in the upper medulla to ascend through the brainstem. Here they lie just medial to the (already crossed) spinothalamic pathway. Brainstem lesions can therefore cause sensory loss affecting all modalities on the contralateral side of the body. Distribution of facial sensory loss due to brainstem lesions arises from the anatomy of the trigeminal fibres within the brainstem. Fibres from the back of the face (near the ears) descend within the brainstem to the upper part of the spinal cord before synapsing, the second-order neurons crossing the midline and then ascending with the spinothalamic fibres. Fibres conveying sensation from more anterior areas of the face descend a shorter distance in the brainstem. Thus, sensory loss in the face from low brainstem lesions is in a ‘balaclava helmet’ distribution, as the longer descending trigeminal fibres are affected. Both dorsal column and spinothalamic tracts end in the thalamus, relaying from there to the parietal cortex.

Pain

Pain is a complex perception that is only partly related to activity in nociceptor neurons (Fig. 8.2). Higher up, chronic and severe pain interacts extensively with mood and can exacerbate or be exacerbated by mood disorder, including depression and anxiety. Modification of psychological and psychiatric sequelae is a vital part of pain management (see Ch. 8).

Sphincter control

The sympathetic supply to the bladder arises from roots T11–L2 to synapse in the inferior hypogastric plexus, while the parasympathetic supply leaves from S2–4. In addition, a somatic supply to the external (voluntary) sphincter arises from S2–4, travelling via the pudendal nerves.

Storage of urine is maintained by inhibiting parasympathetic activity and thus relaxing the detrusor muscle of the bladder wall. Continence is also helped by simultaneous sympathetic- and somatic-mediated tonic contraction of the urethral sphincters. Voiding in adults is usually carried out under conscious control, which triggers relaxation of tonic inhibition on the pontine micturition centre from higher centres, leading to relaxation of the pelvic floor muscles and external and internal urethral sphincters, along with parasympathetic-mediated detrusor contraction.

Personality and mood

The physiology and pathology of mood disorders are discussed elsewhere (Ch. 31) but it is important to remember that any process affecting brain function may influence mood and affect. Conversely, mood disorder may have a significant effect on perception and function. It can be difficult to disentangle whether psychological and psychiatric changes are the cause or the effect of any neurological symptoms.

Sleep

The function of sleep is unknown but it is required for health. Sleep is controlled by the reticular activating system in the upper brainstem and diencephalon. It is composed of different stages that can be visualised on electroencephalography (EEG). As drowsiness occurs, normal EEG background alpha rhythm disappears and activity becomes dominated by deepening slow-wave activity. As sleep deepens and dreaming begins, the limbs become flaccid, movements are ‘blocked’ and EEG signs of rapid eye movements (REM) are superimposed on the slow wave. REM sleep persists for a short spell before another slow-wave spell starts, the cycle repeating several times throughout the night. REM phases lengthen as sleep progresses. REM sleep seems to be the most important part of the sleep cycle for refreshing cognitive processes, and REM sleep deprivation causes tiredness, irritability and impaired judgement.

Localising lesions in the central nervous system

After taking a history and examining the patient, the clinician should have an idea of the nature and site of any pathology (see Box 28.10). Given the intricate anatomy of the brainstem, this section will dwell on the possible localisation in more detail (see Fig. 28.5).

Brainstem lesions typically present with symptoms due to cranial nerve, cerebellar and upper motor neuron dysfunction and are most commonly caused by vascular disease. Since the anatomy of the brainstem is very precisely organised, it is usually possible to localise the site of a lesion on the basis of careful history and examination in order to determine exactly which tracts/ nuclei are affected, usually invoking the fewest number of lesions.

For example, in a patient presenting with sudden onset of upper motor neuron features affecting the right face, arm and leg in association with a left 3rd nerve palsy, the lesion will be in the left cerebral peduncle in the brainstem and the pathology is likely to have been a discrete stroke, as the onset was sudden. Examples of brainstem lesions are listed in Box 28.3. The effects of individual cranial nerve deficits are discussed elsewhere in this chapter in the sections on eye movements, and on facial weakness, sensory loss in brainstem lesions, dysphonia and dysarthria, and bulbar symptoms.

Investigation of neurological disease

Experienced clinicians make most neurological diagnoses on history alone, with a lesser contribution from examination and investigation. As investigations become more complex and more easily available, it is tempting to adopt a ‘scan first, think later’ approach to neurological symptoms. The frequency of ‘false-positive’ results, the wide range of normality and the negative implications for patients (unnecessary expense, inconvenience, discomfort and worry) necessitate a more thoughtful approach. Investigation may include assessment of structure...

(imaging) and function (neuropsychology). Neuropsychological testing has become so complex that in some countries it constitutes a separate specialty focusing on electroencephalography, evoked potentials, nerve conduction studies and electromyography.

**Neuroimaging**

Neurological imaging has traditionally allowed only assessment of structure but advances are allowing much more sophistication. Imaging modalities can use X-rays (plain X-rays, computed tomography (CT), CT angiography, myelography and angiography), magnetic resonance (MR imaging (MRI), MR angiography (MRA)), ultrasound (Doppler imaging of blood vessels) and nuclear medicine techniques (single photon emission computed tomography (SPECT) and positron emission tomography (PET)). The uses and limitations of each of these are shown in Box 28.4. Different sequences for analysing MRI signals can provide helpful information for characterising tissues and pathologies (Box 28.5).
Advanced MR techniques, such as functional MRI (fMRI), MR spectroscopy or diffusion tensor imaging (DTI), can be used to assess brain metabolism and chemical compositions. This may be dynamic and can provide ‘maps’ of cortical function to help plan lesionectomy and epilepsy surgery. Similarly, MR spectroscopy can outline the chemical composition of specific regions, providing notions of whether lesions are ischaemic, neoplastic or inflammatory.

Some degenerative neurological conditions cause functional rather than structural abnormalities that make metabolic and neurochemical assessment increasingly useful. PET scanning can display glucose metabolism in dementia and epilepsy. SPECT scanning uses the lipid-soluble properties of radioactive tracers to mark cerebral blood flow at the time of injection to help in investigating seizures. Dopaminergic pathway tracers can assess the integrity of the nigrostriatal pathway in patients with possible parkinsonism.

**Head and orbit**

Plain skull X-rays now have a very limited role in neurological disease. CT or MRI is needed for intracranial imaging. CT is good for demonstrating bone and calcification well. It will also detect abnormalities of the brain and ventricles, such as atrophy, tumours, cysts, abscesses, vascular lesions and hydrocephalus. Diagnostic yield may be improved by the use of intravenous contrast and thinner slicing but CT is not optimal for lesions of meninges, cranial nerves or subtle parenchymal changes.

MRI resolution is unaffected by bone and so is more useful in posterior fossa disease. Its sensitivity for cortical and white matter changes makes it the modality of choice in inflammatory conditions such as multiple sclerosis and in the investigation of epilepsy. Different MRI techniques can selectively suppress signal from fluid or fat, for example, and so increase sensitivity for more subtle pathologies.

Examples of brain imaged by the various techniques are shown in Figure 28.12.

**Cervical, thoracic and lumbar spine**

X-rays are useful for imaging bony structures and can show destruction or damage to vertebrae, for example, but will provide no information about non-bony tissues, such as intervertebral discs, spinal cord and nerve roots. They have some usefulness in dynamic imaging, e.g. flexion/extension of the spine, in the assessment of instability. MRI has transformed spinal investigation, as it can give information not only about vertebrae and intervertebral discs but also about their effects on the spinal cord and nerve roots. Myelography (usually with CT) is a rarely used invasive technique requiring injection of contrast into the lumbar theca. While outlining the nerve roots and spinal cord provides some detail about abnormal structure, the accuracy and availability of MRI have reduced the need for it. Myelography may still be used where MRI is unavailable, contraindicated, or precluded by a patient’s claustrophobia. Examples of the cervical spine imaged by plain X-rays, myelography and MRI are shown in Figure 28.13.

**Blood vessels**

Imaging of the extra- and intracranial blood vessels and disturbance of arterial or venous blood flow is described on page 1214.
**Neurophysiological testing**

**Electroencephalography**

The electroencephalogram (EEG) detects electrical activity arising in the cerebral cortex via electrodes placed on the scalp to record the amplitude and frequency of the resulting waveforms. With closed eyes, the normal background activity is 8–13 Hz (known as alpha rhythm), most prominent occipitally and suppressed on eye opening. Other frequency bands seen over different parts of the brain in different circumstances are beta (faster than 13/sec), theta (4–8/sec) and delta (slower than 4/sec). Normal EEG patterns evolve with age and alertness; lower frequencies predominate in the very young and during sleep.

In recent years digital technology has allowed longer, cleaner EEG recordings that can be analysed in a number of ways and recorded alongside contemporaneous video of any clinical “event”. Meanwhile,
the development of intracranial recording allows more sensitive monitoring via surgically placed electrodes into and around lesions to help increase the efficacy and safety of epilepsy surgery.

Abnormal EEGs result from a number of conditions. Examples include an increase in fast frequencies (beta) seen with sedating drugs such as benzodiazepines, or marked focal slowing noted over a structural lesion such as a tumour or an infarct. Improved quality and accessibility of imaging have made EEG redundant in lesion localisation, except in the specialist investigation of epilepsy (p. 1155). EEG remains useful in progressive and continuous disorders such as reduced consciousness, encephalitis, and certain dementias, such as Creutzfeldt–Jakob disease.

Since sleep induces marked changes in cerebral activity, EEG can be useful in diagnosis of sleep disturbances. In paroxysmal disorders such as epilepsy, EEG is at its most useful when it captures activity during one of the events in question. Over 50% of patients with epilepsy have a normal ‘routine’ EEG but, conversely, the presence of epileptiform features does not of itself make a diagnosis. Up to 5% of some normal populations may demonstrate epileptiform discharges on EEG, preventing its use as a screening test for epilepsy, most notably in younger patients with a family history of epilepsy. In view of this, the EEG should not be used where epilepsy is merely ‘possible’.

Therefore the EEG in epilepsy is predominantly used for classification and prognostication, but in some patients can help localise the seat of epileptiform discharges when surgery is being considered. During a seizure, high-voltage disturbances of background activity (‘discharges’) are often noted. These may be generalised, as in the 3 Hz ‘spike and wave’ of childhood absence epilepsy, or more focal, as in localisation-related epilepsies (Fig. 28.14). Techniques such as hyperventilation or photic stimulation can be used to increase the yield of epileptiform changes, particularly in the generalised epilepsy syndromes. While some argue that it is possible to detect ‘spikes’ and ‘sharp waves’ to lend support to a clinical diagnosis, these are non-specific and therefore not diagnostic, and can lead an unwaried clinician to err in ascribing other symptoms to epilepsy.

**Nerve conduction studies**

Electrical stimulation of a nerve causes an impulse to travel both efferently and afferently along the underlying axons. Nerve conduction studies (NCS) make use of this, recording action potentials as they pass along peripheral nerves and (with motor nerves) as they pass into the muscle belly. Digital recording has enhanced sensitivity and reproducibility of these tiny potentials. By measuring the time taken to traverse a known distance, it is possible to calculate nerve conduction velocities (NCVs). Healthy nerves at room temperature will conduct at a speed of 40–50 m/sec. If the recorded potential is smaller than expected, this provides evidence of a reduction in the overall number of functioning axons. Significant slowing of conduction velocity, in contrast, suggests impaired conduction due to peripheral nerve demyelination. Such changes in NCS may be diffuse (as in a hereditary demyelinating peripheral neuropathy), focal (as in pressure palsies) or multifocal (e.g. Guillain–Barre syndrome, mononeuropathy multiplex). The information gained can allow the disease responsible for peripheral nerve dysfunction to be better deduced (see Box 28.86).

Stimulation of motor nerves allows for the recording of compound muscle action potentials (CMAPs) over muscles (Fig. 28.15). These are around 500 times larger than sensory nerve potentials, typically around 1–20millivolts. Since a proportion of stimulated impulses in motor nerves will ‘reflect’ back from the anterior horn cell body (forming the ‘F’ wave), it is also possible to obtain some information about the condition of nerve roots.

Repetitive nerve stimulation (RNS) at 3–15/sec provides consistent CMAPs in healthy muscle. In myasthenia gravis (p. 1194), however, where there is partial blockage of acetylcholine receptors, there is a diagnostic fall (decrement) in CMAP amplitude. In contrast, an increasing CMAP with high-frequency RNS is seen in Lambert– Eaton myasthenic syndrome (p. 1198).

**Electromyography**

Electromyography (EMG) is usually performed alongside NCS and involves needle recording of muscle electrical potential during rest and contraction. At rest, muscle is electrically silent but loss of nerve supply causes muscle membrane to become unstable, manifest as fibrillations, positive sharp waves (‘spontaneous activity’) or fasciculations. Motor unit action potentials are recorded during muscle contraction. Axonal loss or destruction will result in fewer motor units. Resultant sprouting of remaining units will lead to increasing size of each individual unit on EMG. Myopathy, in contrast, causes muscle fibre splitting, which results
in a large number of smaller units on EMG. Other abnormal activity, such as myotonic discharges, may signify abnormal ion channel conduction, as in myotonic dystrophy or myotonia congenita.

Specialised single-fibre electromyography (SFEMG) can be used to investigate neuromuscular junction transmission. Measuring ‘jitter’ and ‘blocking’ can identify the effect of antibodies in reducing the action of acetylcholine on the receptor.

## Evoked potentials

The cortical response to visual, auditory or electrical stimulation can be measured on an EEG as an evoked potential (EP). If a stimulus is provided – e.g. to the eye – the tiny EEG response can be discerned when averaging 100–1000 repeated stimuli. Assessing the latency (the time delay) and amplitude can give information about the integrity of the relevant pathway. MRI now provides more information about CNS pathways, thus reducing reliance on EPs. In practice, visual evoked potentials (VEPs) are most commonly used to help differentiate CNS demyelination from small-vessel white-matter changes (Fig. 28.16).

## Magnetic stimulation

Central conduction times can also be measured using electromagnetic induction of action potentials in the cortex or spinal cord by the local application of specialised coils. Again, MRI has made this technique largely redundant, other than for research.

## Routine blood tests

Many systemic conditions that can affect the nervous system can be identified by simple blood tests. Nutritional deficiencies, metabolic disturbances, inflammatory conditions or infections may all present or be associated with neurological symptoms, and basic blood tests (full blood count, erythrocyte sedimentation rate, C-reactive protein, biochemical screening) may provide clues. Specific blood tests will be highlighted in the relevant subsections of this chapter. Human immunodeficiency virus (HIV) infection is an important cause of neurological disease and the clinician should have a low threshold for checking this.

### Immunological tests

Recent developments have seen a host of new immune-mediated conditions emerge in clinical neurology, with antibody targets ranging from muscle and neuromuscular junction disturbance (causing weakness and muscle pain) to specific neural cell surface molecules such as ion channels (causing cognitive decline, epilepsy and psychiatric changes). Examples of autoantibodies that aid diagnosis and may play a disease-causing role include AChR antibodies (myasthenia gravis), Aquaporin 4 and MOG antibodies (neuromyelitis optica), NMDAR, Lgi1 and CASPR2 antibodies (autoimmune encephalitis). Many of these antibodies to neural/glial cell surface antigens are specifically associated with individual neurological syndromes. Many other antibodies against intracellular antigens have also been described, in particular in association with paraneoplastic syndromes, although it is less clear if these antibodies play a causal role in mediating disease.

### Genetic testing

Relevant subsections will detail the increasing numbers of inherited neurological conditions that can now be diagnosed by DNA analysis (p. 52). These include diseases caused by increased numbers of trinucleotide repeats, such as Huntingtin’s disease myotonic dystrophy; and some types of spinocerebellar ataxia. Mitochondrial DNA can also be sequenced to diagnose relevant disorders. Next-generation sequencing technologies including exome sequencing and whole genome sequencing are increasingly employed to identify undiagnosed genetic disease, but expertise is required in their interpretation (see Ch. 3).

### Lumbar puncture

Lumbar puncture (LP) is the technique used to obtain both a CSF sample and an indirect measure of intracranial pressure. After local anaesthetic injection, a needle is inserted between lumbar spinous processes (usually between L3 and L4) through the dura and into the spinal canal. Intracranial pressure can be deduced (if patients are lying on their side) and CSF removed for analysis. CSF pressure measurement is important in the diagnosis and monitoring of idiopathic intracranial hypertension. In this condition, the LP itself is therapeutic.

CSF is normally clear and colourless, and the tests that are usually performed include a naked eye examination of the CSF and centrifugation to determine the colour of the supernatant (yellow, or xanthochromic, some hours after subarachnoid haemorrhage; p. 1214). Measurement of absorption of specific light wavelengths helps quantify the amount of haem metabolites in CSF. Routine analysis involves a cell count, as well as glucose and protein concentrations.

CSF assessment is important in investigating infections (meningitis or encephalitis), subarachnoid haemorrhage and inflammatory conditions. Normal values and abnormalities found in specific conditions are shown in Box 28.6. More sophisticated analysis allows measurement of antibody formation solely within the CNS (oligoclonal bands), genetic analysis (e.g. polymerase chain reaction (PCR) for herpes simplex or tuberculosis), immunological tests (NMDAR, paraneoplastic antibodies), immunophenotyping by fluorescence-activated cell sorting (FACS) and cytology (to detect malignant cells).

If there is a cranial space-occupying lesion causing raised intracranial pressure, LP presents a theoretical risk of downward shift of intracerebral contents, a potentially fatal process known as coning. Consequently, LP is contraindicated if there is any clinical suggestion of raised intracranial pressure (papilloedema), depressed level of consciousness, or focal neurological signs suggesting a cerebral lesion,

---

until imaging (by CT or MRI) has excluded a space-occupying lesion or hydrocephalus. When there is a risk of local haemorrhage (thrombocytopenia, disseminated intravascular coagulation or anticoagulant treatment), then caution should be exercised or specific measures should be taken. LP can be safely performed in patients on low-dose aspirin or low-dose heparin. UK guidelines advise considering pausing other antplatelet agents for a period before elective LP (e.g. 7 days for clopidogrel). LP may be unsafe in patients who are fully anticoagulated due to the increased risk of epidural haematoma and haematoma advice should be sought.

About 30% of LPs are followed by a postural headache, due to reduced CSF pressure. The frequency of headache can be reduced by using smaller oratraumatic needles. Rarer complications involve transient radicular pain, and pain over the lumbar region during the procedure. Aseptic technique renders secondary infections such as meningitis extremely rare.

### Biopsy

Biopsies of nervous tissue (peripheral nerve, muscle, meninges or brain) are occasionally required for diagnosis.

Nerve biopsy can help in the investigation of peripheral neuropathy. Usually, a distal sensory nerve (sural or radial) is targeted. Histological examination can help identify underlying causes, such as vasculitides or infiltrative disorders like amyloid. Nerve biopsy should not be undertaken lightly since there is an appreciable morbidity; it should be reserved for cases where the diagnosis is in doubt after routine investigations and where it will influence management.

Muscle biopsy is performed more frequently and is indicated for the differentiation of myositis and myopathies. These conditions can usually be distinguished by histological examination, and enzyme histochemistry can be useful when mitochondrial diseases and storage diseases are suspected. The quadriceps muscle is most commonly biopsied but other muscles may also be sampled if they are involved clinically. Although pain and infection can follow the procedure, these are less of a problem than after nerve biopsy. Imaging and clinical examination may help guide and determine biopsy site.

Brain biopsy is required when imaging fails to clarify the nature of intracerebral lesions, e.g. in unexplained degenerative diseases such as unusual cases of dementia and in patients with brain tumours. Some biopsies are performed stereotactically through a Burr hole in the skull. Nevertheless, haemorrhage, infection and death still occur and brain biopsy should be considered only if a diagnosis is otherwise elusive. Discussion between neurologist, neuroradiologist, neurosurgeon and neuropathologist is important to ensure maximal diagnostic yield of these samples.
Biopsy of other organs can be useful in the diagnosis of systemic disorders presenting as neurological problems, such as tonsillar biopsy (prion diseases), or rectal or fat biopsy (for assessment of amyloid).

**28.7 How to take a neurological history**

**Introduction**
- Age and sex
- Handedness

**Presenting complaint**
- Symptoms (clarify: see text)
- Overall pattern: intermittent or persistent?
- If intermittent, how often do symptoms occur and how long do they last?
- Speed of onset: seconds, minutes, hours, days, weeks, months, years, decades?
- Better, worse or the same over time?
- Associated symptoms (including non-neurological)
- Disability caused by symptoms
- Change in walking
- Difficulty with fine hand movements, e.g. writing, fastening buttons, using cutlery
- Effect on work, family life and leisure

**Background**
- Previous neurological symptoms and whether similar to current symptoms
- Previous medical history
- Domestic situation
- Driving licence status
- Medications (current and at time of symptom onset)
- Alcohol/smoking habits
- Recreational drug and other toxin exposure
- Family history and developmental history
- What are patient’s thoughts/fears/concerns?

**28.8 The key diagnostic questions**

**Where is the lesion?**
- Is it neurological?
- If so, to which part of the nervous system does it localise?
  - Central versus peripheral

**What is the lesion?**
- Hereditary or congenital
- Acquired:
  - Traumatic
  - Infective
  - Neoplastic
  - Degenerative
  - Inflammatory or immune-mediated
  - Vascular
  - Functional

**28.9 Neurological examination in old age**

- Pupils: tend to be smaller, making fundoscopy more difficult.
- Limb tone: more difficult to assess because of poor relaxation and concomitant joint disease.
- Ankle reflexes: may be absent.
- Gait assessment: more difficult because of concurrent musculoskeletal disease and pre-existing neurological deficits.
- Sensory testing: especially difficult when there is cognitive impairment.
- Vibration sense: may be reduced distally in the legs.

While history is important in all medical specialities, it is especially key in neurology, where many neurological diagnoses have no confirmatory test. History-taking allows doctor and patient to get to know one another; many neurological diseases follow chronic paths and this may be the first of many such consultations. It also allows the clinician to obtain information about the patient’s affect, cognition and psychiatric state.

History-taking is a highly active process. While there are generic templates (Box 28.7), each individual story will follow its own course, and diagnostic considerations during the history will guide further questioning.

It is important to be clear about what patients mean by certain words. They may find it difficult to describe symptoms: for instance, weakness may be called ‘numbness’, while there are many possible interpretations of ‘dizziness’. These must be clarified; even in emergency situations, a clear, accurate history is the foundation of any management plan. While the story should come primarily from the patient, input from eye-witnesses and family members is crucial if the patient is unable to provide details or if there has been loss of consciousness. This need for corroboration and clarification means the telephone is as important as any investigation.

The aim of the history is to address two key issues: (1) where is the lesion; and (2) what is the lesion? (Box 28.8). These should remain uppermost in the doctor’s mind while the history is being elicited, especially in older people (Box 28.9). Some common combinations of symptoms may suggest particular locations for a lesion (Box 28.10). Enquiry about handedness is important; lateralisation of the dominant hand helps designate the dominant hemisphere, which in turn may help to localise any pathologies, or to plan rehabilitation or treatment strategies in asymmetrical disorders such as stroke or Parkinson’s disease.

Epidemiology must be borne in mind. How likely is it that this particular patient has any specific condition under consideration? For example, a 20-year-old with right-sided headache and tenderness will not have temporal arteritis, but this is an important possibility if such symptoms present in a 78-year-old female. Global epidemiology is important and endemic infectious agents and travel history should always be considered.

Determining the evolution, speed of onset and progression of a disease is important (Box 28.11). For example, if right-hand weakness occurred overnight, it would suggest a stroke in an older person or an acute encephalopathy in a younger one. Evolution over several days, however, might indicate demyelination (multiple sclerosis) a possible diagnosis, or perhaps a subdural haematoma if the weakness was preceded by a head injury in an older person taking warfarin. Progression over weeks might bring an intracranial mass lesion or motor neuron disease into the differential. Slow progression over a year or so, with difficulty in using the hand, could suggest a degenerative process such as Parkinson’s disease. The impact on day-to-day activities, such as walking, climbing stairs and carrying out fine hand movements, should also be established in order to gauge the level of associated disability.

Estimates of the frequency and duration of specific events are essential when taking details of a paroxysmal disorder such as migraine and epilepsy. Vague terms such as ‘a lot’ or ‘sometimes’ are unhelpful, and it can assist the patient if choices are given to estimate numbers, such as once a day, week or month.

Many neurological symptoms are not explained by typical neurological disease. Describing these as ‘functional’ is less pejorative, more acceptable to patients and more in keeping with modern understanding of these symptoms than ‘psychogenic’ or ‘hysterical’. Functional symptoms require considerable experience in diagnosis and are frequently missed.
**Headache and facial pain**

Most headaches are chronic disorders but acute presentation of headaches is an important aspect of emergency medical care. Headache may be divided into primary (benign) or secondary, and most patients, whether presenting in clinic or as emergencies, have primary syndromes (see Box 9.13). The emergency clinical assessment of headaches is dealt with on page 186.

**Ocular pain**

Assuming that ocular disease (such as acute glaucoma) has been excluded, ocular pain may be due to trigeminal autonomic cephalalgias (TACs) or, rarely, inflammatory or infiltrative lesions at the apex of the orbit or the cavernous sinus, when 3rd, 4th, 5th or 6th cranial nerve involvement is usually evident. Ocular pain and headache are also discussed on page 1223.

**Facial pain**

Pain in the face can be due to dental or temporomandibular joint problems. Acute sinusitis is usually apparent from other features of sinus congestion/infection and may cause localised pain over the affected sinus, but is almost never the explanation for persistent facial pain or headache.

Facial pain is not uncommon in migraine but some syndromes can present solely with facial pain. The most common neurological causes of facial pain are trigeminal neuralgia, herpes zoster (shingles) and post-herpetic neuralgia, all characterised by their extreme severity. In trigeminal neuralgia, the patient describes bouts of brief (seconds), lancinating pain (‘electric shocks’), most frequently felt in the second and third divisions of the nerve and often triggered by talking or chewing. Facial shingles most commonly affects the first (ophthalmic) division of the trigeminal nerve, and pain usually precedes the rash. Post-herpetic neuralgia may follow, typically a continuous burning pain throughout the affected territory, with marked sensitivity to light touch (allodynia) and resistance to treatment. Destructive lesions of the trigeminal nerve usually cause numbness rather than pain.

**Dizziness, blackouts and ‘funny turns’**

Acute onset of dizziness or blackouts will present to the acute medical department. In neurological practice, it is common to deal with patients presenting with a history of multiple events. While detailed questioning will be dealt with in the relevant section (see p. 185), the neurologist will have to tease out the pattern of each of the different attack types experienced by the patient to be able to form a treatment and investigation plan, one of the challenges of clinical neurology.

**Status epilepticus**

Status epilepticus is seizure activity not resolving spontaneously, or recurrent seizure with no recovery of consciousness in between. Persisting seizure activity has a recognised mortality and is a medical emergency.

Diagnosis is usually clinical and can be made on the basis of the description of prolonged rigidity and/or clonic movements with loss of awareness. As seizure activity becomes prolonged, movements may
become more subtle. Cyanosis, pyrexia, acidosis and sweating may occur, and complications include aspiration, hypotension, cardiac arrhythmias and renal or hepatic failure.

In patients with pre-existing epilepsy, the most likely cause is a fall in antiepileptic drug levels. In de novo status epilepticus, it is essential to exclude precipitants such as infection (meningitis, encephalitis), neoplasia and metabolic derangement (hypoglycaemia, hypoponatraemia or hypocalcaemia). Treatment and investigation are outlined in Box 28.12.

Coma

Coma and loss of consciousness usually present to the acute medical admissions department (p. 197). Clarification of cause and prognosis may require specialist neurological input.

Delirium

Delirium describes cortical dysfunction and replaces the older term ‘acute confusional state’. It has a range of primary causes, and given its role in precipitating acute admission, it is covered in detail on page 213.

Amnesia

Memory disturbance is a common symptom. In the absence of significant functional impairment (e.g. inability to work, dyspraxias, loss of daily function), many patients will prove to have benign memory dysfunction related to age, mood or psychiatric disorders. Investigation and treatment of the dementias are discussed elsewhere (p. 1246).

Temporary loss of memory may be due to a transient delirium related to infection, the post-ictal period after seizure, or transient global amnesia. These are usually distinguished on the basis of the history. Transient amnesia resulting directly from a seizure (transient epileptic amnesia) is a rare result of temporal lobe epilepsy.

Transient global amnesia (TGA) predominantly affects middle-aged people, with an abrupt, discrete loss of anterograde memory function lasting up to a few hours. During the episode, patients are unable to record new memories, resulting in repetitive questioning, the hallmark of this condition. Consciousness is preserved and patients may perform even complex motor acts normally. During the attack there is retrograde amnesia for the events of the past few days, weeks or years. After 4–6 hours, memory function and behaviour return to normal but the patient has persistent, complete amnesia for the duration of the attack itself. There are no seizure markers and, unlike epileptic amnesia, transient global amnesia recurs in only around 10%–20% of cases. A vascular aetiology is unlikely (TGA is not a risk factor for subsequent vascular disease) and amnesia may be due to a benign process similar to migraine, occurring in the hippocampus. TGA causes no physical signs and, provided there is a typical history (which requires a witness), no investigation is necessary and patients may be reassured.

Persistent amnesia

Serious neurological disease must be excluded in patients with persistent memory disturbance, although many will prove to have benign symptoms. Symptoms corroborated by relatives or colleagues are likely to be more significant than those noted by the patient only. Where poor concentration is at the heart of cognitive deterioration, it is more likely to be due to an underlying mood disorder.

It is important to assess the timing of onset and to establish which aspects of memory are affected. Complaints of getting lost or of losing complex abilities are more pathological than word-finding difficulties. Disturbance of episodic or working memory (previously called ‘short-term memory’) must be distinguished from semantic memory (memory for concept-based knowledge unrelated to specific experiences). Episodic memory is selectively impaired in Korsakoff syndrome (often secondary to alcohol) or bilateral temporal lobe damage. It can also be seen in conjunction with other types of dementia. Progressive deterioration over months suggests an underlying dementia, and a full medical assessment must be performed to detect any underlying medical problem.

It is important to identify and treat depression in patients with memory loss. Depression may present as a ‘pseudo-dementia’, with concentration and memory impairment as dominant features, and this is often reversible with antidepressant medication. Any patient with dementia (particularly of Alzheimer type) may develop depression in the early stages of their illness, however. Specific causes of progressive dementia, with their investigation and treatment, are described elsewhere (p. 1246).

Weakness

The assessment of weakness requires the application of basic anatomy, physiology and some pathology to the interpretation of the history and clinical findings. Points to consider are shown on Figure 28.17 and in Boxes 28.13 and 28.14. The pattern and evolution of weakness and the clinical signs provide clues to the site and nature of the lesion.
28.13 Distinguishing signs in upper versus lower motor neuron syndromes

It is important to establish whether the patient has loss of power rather than reduced sensation or generalised fatigue. Pain may restrict movement and thus mimic weakness. Paradoxically, sensory neglect may leave patients unaware of severe weakness.

Patients with parkinsonism may complain of weakness; extrapyramidal signs of rigidity (cogwheel or lead pipe) and bradykinesia should be evident, and a resting tremor (usually asymmetrical) may provide a further clue. Simple observation of the patient walking into the consulting room may be diagnostic and is as important as formal strength testing. Movement restricted by pain should be apparent, and other features (contractures, wasting, fasciculations, abnormal movements/postures) all provide diagnostic clues.

Weakness is a common symptom arising without an underlying degenerative or destructive cause (functional symptom). Functional weakness does not conform to typical patterns, and the signs in Box 28.13 are absent. Clinical examination is often variable (e.g., the patient can walk but appears to have no leg movement when assessed on the couch), and strength may appear to ‘give way’, with the patient able to achieve full power for brief bursts, which does not occur in disease. Hoover’s sign is useful to confirm functional weakness and relies on eliciting the normal phenomenon of simultaneous hip extension when the contralateral hip flexes. In functional weakness, hip extension
weakness may be seen; this then returns to full strength when contralateral hip flexion is tested. This sign may be demonstrated to the patient in a non-confrontational manner, to show that potential limb power is intact.

**Facial weakness**

**Facial nerve palsy (Bell’s palsy)**

One of the most common causes of facial weakness is Bell’s palsy, a lower motor neuron lesion of the 7th (facial) nerve, affecting all ages and both sexes. It is more common following upper respiratory tract infections, during pregnancy and in patients with diabetes, immunosuppression and hypertension. It is common in human immunodeficiency virus at the time of seroconversion.

The lesion is within the facial canal. Symptoms usually develop subacutely over a few hours, with pain around the ear preceding the unilateral facial weakness. Patients often describe the face as ‘numb’ but there is no objective sensory loss (except to taste, if the chorda tympani is involved). Hyperacusis may occur if the nerve to stapedius is involved and impairment of parasympathetic fibres may cause diminished salivation and tear secretion. Examination reveals an ipsilateral lower motor neuron facial nerve palsy (no sparing of forehead muscles). Vesicles in the ear or on the palate may indicate primary herpes zoster infection. A clinical search for signs of other causes of lower motor neuron facial nerve weakness, such as parotid or scalp lesions, trauma or skull base lesions, is justified.

Glucocorticoids improve recovery rates if started within 72 hours of onset but antiviral drugs are not effective. Artificial tears applied regularly prevent corneal drying, and tapping the eye shut overnight helps prevent exposure keratitis and corneal abrasion. Patients unable to close the eye should be referred urgently to an ophthalmologist. About 80% of patients recover spontaneously within 12 weeks. Plastic surgery may be considered for the minority left with facial disfigurement after 12 months. Recurrence is unusual and should prompt further investigation. Aberrant re-innervation may occur during recovery, producing unwanted facial movements, such as eye closure when the mouth is moved (synkinesis) or ‘crocodile tears’ (tearing during salivation).

Unlike Bell’s palsy, lesions with an upper motor neuron origin may spare the upper face. Cortical lesions may cause a facial weakness either in isolation or with associated hemiparesis and speech difficulties.

**Sensory disturbance**

Sensory symptoms are common and frequently benign. Patients often find sensory symptoms difficult to describe and sensory examination is difficult for both doctor and patient. While neurological disease can cause sensory symptoms, systemic disorders can also be responsible. Tingling in both hands and around the mouth can occur as the result of hyperventilation or hypocapaeemia. When there is dysfunction of the relevant cerebral cortex, the patient’s perception of the wholeness or actual presence of the relevant part of the body may be distorted.

**Numbness and paraesthesia**

The history may give the best clues to localisation and pathology. Certain common patterns are recognised: in migraine, the aura may consist of spreading tingling or paraesthesia, followed by numbness evolving over 20–30 minutes over one half of the body, often splitting the tongue. Sensory loss caused by a stroke or transient ischaemic attack (TIA) occurs much more rapidly and is typically negative (numbness) rather than positive (tingling). Rarely, unpleasant paraesthesia of sensory epilepsy spreads within seconds. The sensory alteration of inflammatory spinal cord lesions often ascends from one or both lower limbs to a distinct level on the trunk over hours to days, and can give rise to a feeling of constriction, sometimes described as “being hugged”. Sensory change can occur as a manifestation of anxiety or as part of a functional neurological disorder. In such cases, the distribution usually neither conforms to a known anatomical pattern nor fits with any typical neurological disease. Care must be taken in diagnosing functional sensory problems; a careful history and examination will ensure there is no other objective neurological deficit.

Sensory neurological examination needs to be undertaken and interpreted with care because the findings depend, by definition, on subjective reports. The reported distribution of sensory loss can be useful, however, when combined with the coexisting deficits of motor and/or cranial nerve function (Fig. 28.18).

**Sensory loss in peripheral nerve lesions**

Here the symptoms are usually of sensory loss and paraesthesia. Single nerve lesions cause disturbance in the sensory distribution of the nerve, whereas in diffuse neuropathies the longest neurons are affected first, giving a characteristic ‘glove and stocking’ distribution. If smaller nerve fibres are preferentially affected (e.g. in diabetic neuropathy), temperature and pin-prick (pain) are reduced, whilst vibration sense and proprioception (modalities served by the larger, well-myelinated, sensory nerves) may be relatively spared. In contrast, vibration and proprioception are particularly affected if the neuropathy is demyelinating in character, producing symptoms of tightness and swelling with impairment of proprioception and vibration sensation.

**Sensory loss in nerve root lesions**

These typically present with pain as a prominent feature, either within the spine or in the limb plexuses. Pain is often felt in the myotome rather than the dermatome. The nerve root involved may be deduced from the dermatomal pattern of sensory loss, although overlap may lead to this being smaller than expected.

**Sensory loss in spinal cord lesions**

Transverse lesions of the spinal cord produce loss of all sensory modalities below that segmental level, although the clinical level may only be manifest 2–3 segments lower than the anatomical site of the lesion. Very often, there is a band of paraesthesia or hyperaesthesia at the top of the area of sensory loss. Clinical examination may reveal dissociated sensory loss, i.e. different patterns in the spinothalamic and dorsal columnar pathways. If the transverse lesion is vascular due to anterior spinal artery thrombosis, the spinothalamic pathways may be affected while the posterior one-third of the spinal cord (the dorsal column modalities) may be spared.

Lesions damaging one side of the spinal cord will produce loss of spinothalamic modalities (pain and temperature) on the opposite side, and of dorsal column modalities (joint position and vibration sense) on the same side of the body – the Brown–Séquard syndrome (see Fig. 28.18E).

Lesions in the centre of the spinal cord (such as syringomyelia: see Box 28.82 and Fig. 28.49) spare the dorsal columns but involve the spinothalamic fibres crossing the cord from both sides over the length of the lesion. There is no sensory loss in segments above and below the lesion; this is described as ‘suspended’ sensory loss. There is sometimes reflex loss at the level of the lesion if afferent fibres of the reflex arc are affected.

An isolated lesion of the dorsal columns is not uncommon in multiple sclerosis. This produces a characteristic unpleasant, tight feeling over the limb(s) involved and, while there is no loss of pin-prick or temperature sensation, the associated loss of proprioception may severely limit function of the affected limb(s).

**Sensory loss in brainstem lesions**

Lesions in the brainstem can be associated with sensory loss but the distribution depends on the site of the lesion. A lesion limited to the trigeminal nucleus or its sensory projections will cause ipsilateral facial sensory disturbance. For example, pain resembling trigeminal neuralgia can be seen in patients with multiple sclerosis. The anatomy of the trigeminal connections means that lesions in the medulla or spinal cord can give rise to “balaclava helmet” patterns of sensory loss. Sensory pathways running up from the spinal cord can also be damaged in the brainstem, resulting in simultaneous sensory loss in arm(s) and/or leg(s).
Sensory loss in hemispheric lesions

The temporal, parietal and occipital lobes receive sensory information regarding the various modalities of touch, vision, hearing and balance (see Box 28.2). The initial points of entry into the cortex are the respective primary cortical areas (see Fig. 28.4). Damage to any of these primary areas will result in reduction or loss of the ability to perceive that particular modality: ‘negative’ symptomatology. Abnormal excitation of these areas can result in a false perception (‘positive’ symptoms), the most common of which is migrainous visual aura (flashing lights or teichopsia).

Cortical lesions are more likely to cause a mixed motor and sensory loss. Substantial lesions of the parietal cortex (as in large strokes) can cause severe loss of proprioception and may even abolish conscious awareness of the existence of the affected limb(s), known as neglect; this can be difficult to distinguish from paralysis. Pathways are so tightly packed in the thalamus that even small lacunar strokes can cause isolated contralateral hemisensory loss.

Neuropathic pain

Neuropathic pain is a positive neurological symptom caused by dysfunction of the pain perception apparatus, in contrast to nociceptive pain, which is secondary to pathological processes such as inflammation. Neuropathic pain has distinctive features and typically provokes a very unpleasant, persistent, burning sensation. There is often increased sensitivity to touch, so that light brushing of the affected area causes exquisite pain (allodynia). Painful stimuli are felt as though they arise from a larger area than that touched, and spontaneous bursts of pain may also occur. Pain may be elicited by other modalities (alldynia) and is considerably affected by emotional influences. The most common causes of neuropathic pain are diabetic neuropathies, trigeminal and post-herpetic neuralgias, and trauma to a peripheral nerve. Treatment of these syndromes can be difficult. Drugs that modulate various parts of the nociceptive system, such as gabapentin, carbamazepine or tricyclic antidepressants, may help. Localised treatment (topical treatment or nerve blocks) sometimes succeeds but may increase the sensory deficit and worsen the situation. Electrical stimulation has occasionally proved successful.

Abnormal movements

Disorders of movement lead to either extra, unwanted movement (hyperkinetic disorders) or too little movement (hypo-kinetic disorders) (Box 28.15). In either case, the lesion often localises to the basal ganglia, although some tremors are related to cerebellar or brainstem disturbance. Functional movement disorders are common and may mimic all of the organic syndromes below. The most important hypokinetic disorder is Parkinson’s disease. Parkinsonism is a clinical description of a collection of symptoms, including tremor, bradykinesia and rigidity. While the history is always important, observation is clearly vital; much of the skill in diagnosing movement disorders lies in pattern recognition. Once it is established whether the problem is hypo- or hyperkinetic, the next task is to categorise the movements further, accepting that there is often overlap. Videoing the movements (with the patient’s consent), so that they can be shown to a movement disorder expert, may provide a quick diagnosis in cases of uncertainty.

Tremor

Tremor is caused by alternating agonist/antagonist muscle contractions and produces a rhythmic oscillation of the body part affected. In the assessment of tremor, the position, body part affected, frequency and amplitude should be considered, as these provide diagnostic clues (Box 28.16).

Other hyperkinetic syndromes

Non-rhythmic involuntary movements include chorea, athetosis, ballism, dystonia, myoclonus and tics. They are categorised by clinical appearance, and coexistence and overlap are common, such as in choreoathetosis.
Chorea

Chorea (from the Greek word ‘dance’) refers to abrupt, brief, irregular, purposeless involuntary movements, appearing fidgety and clumsy and affecting different areas. They suggest disease in the caudate nucleus (as in Huntington’s disease) and are a common complication of levodopa treatment for Parkinson’s disease. Other causes are shown in Box 28.17.

Athetosis

Slower, writhing movements of the limbs are often combined with chorea and have similar causes.

Ballism

This more dramatic form of chorea causes often violent flinging movements of one limb (monoballism) or one side of the body (hemiballism). The lesion localises to the contralateral subthalamic nucleus and the most common cause is stroke.

Dystonia

Sustained involuntary muscle contraction causes abnormal postures or movement. It may be generalised (usually in childhood-onset genetic syndromes) or, more commonly, focal/segmental (such as in torticollis, when the head is twisted repeatedly to one side). Some dystonias occur only with specific tasks, such as writer’s cramp or other occupational ‘cramps’. Dystonic tremor is associated, is asymmetrical and of large amplitude.

**Myoclonus**

Myoclonus consists of brief, isolated, random jerks of muscle groups. This is physiological at the onset of sleep (hypnic jerks). Similarly, a myoclonic jerk is a component of the normal startle response, which may be exaggerated in some rare (mostly genetic) disorders. Myoclonus may occur in disorders of the cerebral cortex, such as some forms of epilepsy. Alternatively, myoclonus can arise from subcortical structures or, more rarely, from segments of the spinal cord.

**Tics**

Tics are stereotyped repetitive movements, such as blinking, winking, head shaking or shoulder shrugging. Unlike dyskinesias, the patient may be able to suppress them, although only for a short time. Isolated tics are common in childhood and usually disappear. Tourette syndrome is defined by the presence of multiple motor and vocal tics that may evolve over time; it is frequently associated with psychiatric disease, including obsessive compulsions, depression, self-harm or attention deficit disorder. Tics may also occur in Huntington’s and Wilson’s diseases, or after streptococcal infection.

**Abnormal perception**

The parietal lobes are involved in the higher processing and integration of primary sensory information. This takes place in areas referred to as ‘association’ cortex, damage to which gives rise to sensory (including visual) inattention, disorders of spatial perception and disruption of spatially orientated behaviour, leading to apraxia’s. Apraxia is the inability to perform complex, organised activity in the presence of normal basic motor, sensory and cerebellar function (after weakness, numbness and ataxia have been excluded as causes). Examples of complex motor activities include dressing, using cutlery and geographical orientation. Other abnormalities that can result from damage to the association cortex involve difficulty reading (dyslexia) or writing (dysgraphia), or the inability to recognise familiar objects (agnosia). The results of damage to particular lobes of the brain are given in Box 28.2.

**Altered balance and vertigo**

Balance is a complicated dynamic process that requires ongoing modification of both axial and limb muscles to compensate for the effects of gravity and alterations in body position and load (and hence centre of gravity) in order to prevent a person from falling. This requires input from a variety of sensory modalities (visual, vestibular and proprioceptive), processing by the cerebellum and brainstem, and output via a number of descending pathways (e.g. vestibulospinal, rubrospinal and reticulospinal tracts).

Disorders of balance can therefore arise from any part of this process. Disordered input (loss of vision, vestibular disorders or lack of joint position sense), processing (damage to vestibular nuclei or cerebellum) or motor function (spinal cord lesions, leg weakness of any cause) can all impair balance. The patient may complain of different symptoms, depending on the location of the lesion. For example, loss of joint position sense or cerebellar function may result in a sensation of unsteadiness, while damage to the vestibular nuclei or labyrinth may result in an illusion of movement, such as vertigo (see below). A careful history is vital. Since vision can often compensate for lack of joint position sense, patients with peripheral neuropathies or dorsal column loss will often find their problem more noticeable in the dark.

Examination of such patients may yield physical signs that again depend on the site of the lesion. Sensory abnormalities may be manifest as altered visual acuities or visual fields, possibly with abnormalities on fundoscopy, altered eye movements (including nystagmus, impaired vestibular function or lack of joint position sense). Disturbance of cerebellar function may be manifest as nystagmus, dysarthria or ataxia, or difficulty with gait (unsteadiness or inability to perform tandem gait; see below). Leg weakness, if present, will be detectable on examination of the limbs.

**Vertigo**

Vertigo is defined as an abnormal perception of movement of the environment or self, and occurs because of conflicting visual, proprioceptive and vestibular information about a person’s position in space. Vertigo commonly arises from imbalance of vestibular input and is within the experience of most people, since this is the ‘dizziness’ that occurs after someone has spun round vigorously and then stops. Bilateral labyrinthine dysfunction often causes some unsteadiness. Labyrinthine vertigo usually lasts days at a time, though it may recur, while vertigo arising from central (brainstem) disorders is often persistent and accompanied by other brainstem signs. Benign paroxysmal positional vertigo lasts a few seconds on head movement. A careful history will reveal the likely cause in most patients.

**Abnormal gait**

Many neurological disorders can affect gait. Observing patients as they walk into the consulting room can be very informative, although formal examination is also important. Neurogenic gait disorders need to be distinguished from those due to skeletal abnormalities, usually characterised by pain producing an antalgic gait, or limp. Gait alteration incompatible with any anatomical or physiological deficit may be due to functional disorders.

**Pyramidal gait**

Upper motor neuron lesions cause characteristic extension of the affected leg. The resultant tendency for the toes to strike the ground on walking requires the leg to swing outwards at the hip (circumduction). Nevertheless, a shoe on the affected side worn down at the toes may provide evidence of this type of gait. In hemiplegia, the asymmetry between affected and normal sides is obvious on walking, but in paraparesis both lower limbs swing slowly from the hips in extension and are dragged stiffly over the ground – described as ‘walking in mud’.

**Foot drop**

In normal walking, the heel is the first part of the foot to hit the ground. A lower motor neuron lesion affecting the leg will cause weakness of ankle dorsiflexion, resulting in a less controlled descent of the foot, which makes a slapping noise as it hits the ground. In severe cases, the foot will have to be lifted higher at the knee to allow room for the inadequately dorsiflexed foot to swing through, resulting in a high-stepping gait.

**Myopathic gait**

During walking, alternating transfer of the body’s weight through each leg requires adequate hip abduction. In proximal muscle weakness, usually caused by muscle disease, the hips are not properly fixed by these muscles and trunk movements are exaggerated, producing a rolling or waddling gait.

**Ataxic gait**

An ataxic gait can result from lesions in the cerebellum, vestibular apparatus or peripheral nerves. Patients with lesions of the central portion of the cerebellum (the vermis) walk with a characteristic broad-based gait ‘as if drunk’ (cerebellar function is particularly sensitive to alcohol). Patients with acute vestibular disturbances walk similarly but the accompanying vertigo is characteristic. Inability to walk heel to toe may be the only sign of less severe cerebellar dysfunction.

Proprioceptive defects can also cause an ataxic gait. The impairment of joint position sense makes walking unreliable, especially in poor light. The feet tend to be placed on the ground with greater emphasis, presumably to enhance proprioceptive input, resulting in a ‘stamping’ gait.
**Apraxic gait**
In an apraxic gait, power, cerebellar function and proprioception are normal on examination of the legs. The patient may be able to carry out complex motor tasks (e.g. bicycling motion) while recumbent and yet cannot formulate the motor act of walking. In this higher cerebral dysfunction, the feet appear stuck to the floor and the patient cannot walk. Gait apraxia is a sign of diffuse bilateral hemisphere disease (such as normal pressure hydrocephalus) or diffuse frontal lobe disease.

**Marche à petits pas**
This gait is characterised by small, slow steps and marked instability. It differs from the festination found in Parkinson’s disease (see below), in that it lacks increasing pace and freezing. The usual cause is small-vessel cerebrovascular disease and there may be accompanying bilateral upper motor neuron signs.

**Extrapyramidal gait**
The rigidity and bradykinesia of basal ganglia dysfunction lead to a stooped posture and characteristic gait difficulties, with problems initiating walking and controlling the pace of the gait. Patients may become stuck while trying to start walking or when walking through doorways (‘freezing’). The centre of gravity will be moved forwards to aid propulsion, which, with poor axial control, can lead to an accelerating pace of shuffling and difficulty stopping. This produces the festinant gait: initial staggering steps that quickly increase in frequency while decreasing in length.

**Abnormal speech and language**
Speech disturbance may be disruption of sound output (dysarthria) or may involve language disturbance (dysphasia). Dysphonia (reduction in the sound/volume) is usually due to mechanical laryngeal disruption, whereas dysarthria is more typically neurological in origin. Dysphasia is always neurological and localises to the dominant cerebral hemisphere (usually left, regardless of handedness). Combinations of speech and swallowing problems are explained below.

**Dysphonia**
Dysphonia describes hoarse or whispered speech. The most common cause is laryngitis, but dysphonia can also result from a lesion of the 10th cranial nerve or disease of the vocal cords, including laryngeal dystonia. Parkinsonism may cause hypophonia with marked reduction in speech volume, often in association with dysarthria, making speech difficult to understand.

**Dysarthria**
Dysarthria is characterised by poorly articulated or slurred speech and can occur in association with lesions of the cerebellum, brainstem and lower cranial nerves, as well as in myasthenia or myopathic disease. Language function is not affected. The quality of the speech tends to differ, depending on the cause, but it can be very difficult to distinguish the different types clinically (Box 28.18). Dysarthria is discussed further in the section on bulbar symptoms below.

**Dysphasia**
Dysphasia (or aphasia) is a disorder of the language content of speech. It can occur with lesions over a wide area of the dominant hemisphere (Fig. 28.19). Dysphasia may be categorised according to whether the speech output is fluent or non-fluent. Fluent aphasia, also called receptive aphasia, are impairments related mostly to the input or reception of language, with difficulties either in auditory verbal comprehension or in the repetition of words, phrases or sentences spoken by others. Speech is easy and fluent but there are difficulties related to the output of language as well, such as paraphasia (either substitution of similar-sounding non-words, or incorrect words) and neologisms (non-existent words).

Non-fluent aphasia, also called expressive aphasia, are difficulties in articulating, but in most cases there is relatively good auditory verbal comprehension. Examples include Broca aphasia (associated with pathologies in the inferior frontal region), transcortical motor aphasia and global aphasia.

‘Pure’ aphasia are selective impairments in reading, writing or the recognition of words. These disorders may be quite selective. For example, a person is able to read but not write, or is able to write but not read. Examples include pure alexia, agraphia and pure word deafness.

---

**Fig. 28.19 Classification of cortical speech problems.** (1) Wernicke’s aphasia: fluent dysphasia with poor comprehension and poor repetition. (2) Conduction aphasia: fluent aphasia with good comprehension and poor repetition. (3) Broca’s aphasia: non-fluent aphasia with good comprehension and poor repetition. (4) Transcortical sensory aphasia: fluent aphasia with poor comprehension and good repetition. (5) Transcortical motor aphasia: non-fluent aphasia with good comprehension and good repetition. Large lesions affecting all of regions 1–5 cause global aphasia.

Dysphasia (a focal symptom) is frequently misinterpreted as disorientation (which is non-focal) and it is important always to consider dysphasia as an alternative explanation for the apparently ‘confused’ patient. Dysphasia can be misheard/misspelt as dysphagia, and for this reason some prefer to use ‘aphasia’ to avoid confusion.

**Disturbance of smell**

Symptomatic olfactory loss is most commonly due to local causes (nasal obstruction) but may follow head injury. Hyposmia may predate motor symptoms in Parkinson’s disease by many years, although it is rarely noticed by the patient. Frontal lobe lesions are a rare cause. Positive olfactory symptoms may arise in Alzheimer’s disease or epilepsy.

**Visual disturbance and ocular abnormalities**

Disturbances of vision may be due to primary ocular disease or to disorders of the central connections and visual cortex. Visual symptoms are usually negative (loss of vision) but sometimes positive, most commonly in migraine. Eye movements may be disturbed, giving rise to double vision (diplopia) or blurred vision. Loss of vision is also discussed on page 1224.

**Visual loss**

Visual loss can occur as the result of lesions in any areas between the retina and the visual cortex. Patterns of visual field loss are explained by the anatomy of the visual pathways (see Fig. 28.7). Associated clinical manifestations are described in Box 30.8. Visual symptoms affecting one eye only are due to lesions anterior to the optic chiasm.

Transient visual loss is quite common and sudden-onset visual loss lasting less than 15 minutes is likely to have a vascular origin. It may be difficult to know whether the visual loss was monocular (carotid circulation) or binocular (vertebrobasilar circulation), and it is important to ask if the patient tried closing each eye in turn to see whether the symptom affected one eye or both. Visual field testing is an important part of the examination, either at the bedside or formally with perimetry. Field defects become more symmetrical (congruous), the closer the lesion comes to the visual cortex.

Migrainous visual symptoms are very common and, when associated with typical headache and other migraine features, rarely pose a diagnostic challenge. They may occur in isolation, however, making distinction from TIA difficult, but TIAs typically cause negative (blindness) symptoms, whereas migraine causes positive phenomena (see below). TIAs often last for a shorter time (a few minutes), compared to the 10–60-minute duration of migraine aura, and have an abrupt onset and end, unlike the gradual evolution of a migraine aura.

**Positive visual phenomena**

The most common cause is migraine; patients may describe silvery zigzag lines (fortification spectra) or flashing coloured lights (teichopsia), usually preceding the headache. Simple flashes of light (phosphenes) may indicate damage to the retina (e.g. detachment) or to the primary visual cortex. Formed visual hallucinations may be caused by drugs or may be due to epilepsy or ‘release phenomena’ in a blind visual field (Charles Bonnet syndrome).

**Double vision**

Diplopia arises from misalignment of the eyes, meaning that the image is not projected to the same points on the two retinas. At its most subtle it may be reported as blurred rather than double vision. Monocular diplopia indicates ocular disease, while binocular diplopia suggests a neurological cause. Closing either eye in turn will abort binocular diplopia. Once the presence of binocular diplopia is confirmed, it should be established whether the diplopia is maximal in any particular direction of gaze, whether the images are separated horizontally or vertically, and whether there are any associated symptoms or signs, such as ptosis or pupillary disturbance.

Binocular diplopia may result from central disorders or from disturbance of the ocular motor nerves, muscles or the neuromuscular junction (see Fig. 28.8). The pattern of double vision, along with any associated features, usually allows the clinician to infer which nerves/muscles are affected, while the mode of onset and other features (e.g. fatigability in myasthenia) provide further clues to the cause.

The causes of ocular motor nerve palsies are listed in Box 28.19. Examination findings are illustrated in Figure 28.20.

Nystagmus

Nystagmus describes a repetitive to-and-fro movement of the eyes. In central lesions, the slow drifts are the primary abnormal movement, each followed by fast (corrective) phases. Nystagmus occurs because the control systems of the eyes are defective, causing them to drift off target; corrections then become necessary to return fixation to the object of interest, causing nystagmus. The direction of the fast phase is usually designated as the direction of the nystagmus because it is easier to see. Nystagmus may be horizontal, vertical or torsional, and usually involves both eyes synchronously. It may be a physiological phenomenon in response to sustained vestibular stimulation or movement of the visual world (optokinetic nystagmus). There are many causes of pathological nystagmus, the most common sites of lesions being the vestibular system, brainstem and cerebellum.

The brainstem and the cerebellum are involved in maintaining eccentric positions of gaze. Lesions will therefore allow the eyes to drift back in towards primary position, producing nystagmus with fast component beats in the direction of gaze (gaze-evoked nystagmus). This is the most common type of ‘central’ nystagmus; it is most commonly bidirectional and not usually accompanied by vertigo. Other signs of brainstem dysfunction may be evident. Brainstem disease may also cause vertical nystagmus.

Unilateral cerebellar lesions may result in gaze-evoked nystagmus when looking in the direction of the lesion, where the fast phases are directed towards the side of the lesion. Cerebellar hemispheres also cause ‘ocular dysmetria’, an overshoot of target-directed, fast eye movements (saccades) resembling ‘past-pointing’ in limbs.

In vestibular lesions, damage to one of the horizontal canals or its connections will allow the tonic output from the healthy contralateral side to cause the eyes to drift towards the side of the lesion. This elicits recurrent compensatory fast movements away from the side of the lesion, manifest as unidirectional horizontal nystagmus. Vertical and torsional components can be seen with damage to other parts of the vestibular apparatus. The nystagmus of peripheral labyrinthine lesions is accompanied by vertigo and usually by nausea, vomiting and unsteadiness, but as the CNS habituates, the nystagmus disappears (fatigues) quite quickly. Central vestibular nystagmus is more persistent.

Nystagmus also occurs as a consequence of drug toxicity and nutritional deficiency (e.g. thiamin). The severity is variable, and it may or may not result in visual degradation, though it may be associated with a sensation of movement of the visual world (oscillopsia). Nystagmus may occur as a congenital phenomenon, in which case both phases are equal and ‘pendular’, rather than having alternating fast and slow components.

Ptosis

Various disorders may cause drooping of the eyelids (ptosis) and these are listed in Box 28.20 and shown on Figure 28.21.

Abnormal pupillary responses

Abnormal pupillary responses may arise from lesions at several points between the retina and brainstem. Lesions of the oculomotor nerve, ciliary ganglion and sympathetic supply produce characteristic ipsilateral disorders of pupillary function. ‘Afferent’ defects result from damage to an optic nerve, impairing the direct response of a pupil to light, although leaving the consensual response from stimulation of the normal eye intact. Structural damage to the iris itself can also result in pupillary abnormalities. Causes are given in Box 28.21. An example is shown in Figure 28.22.

Papilloedema

There are several causes of swelling of the optic disc but the term ‘papilloedema’ is reserved for swelling secondary to raised intracranial pressure, when obstructed axoplasmic flow from retinal ganglion cells results in swollen nerve fibres, which in turn cause capillary and venous congestion, producing papilloedema. Lack of papilloedema never excludes raised intracranial pressure. Optic disc swelling and papilloedema are also discussed on page 1226.

Optic atrophy

See Chapter 30.

Hearing disturbance

Each cochlear organ has bilateral cortical representation, so unilateral hearing loss is a result of peripheral organ damage. Bilateral hearing dysfunction is usual and is most commonly due to age-related degeneration or noise damage, although infection and drugs (particularly diuretics and aminoglycoside antibiotics) can be a primary cause. Prominent deafness may suggest a mitochondrial disorder (see Box 28.92).

Bulbar symptoms – dysphagia and dysarthria

Swallowing is a complex activity involving the coordinated action of lips, tongue, soft palate, pharynx and larynx, which are innervated by cranial nerves 7, 9, 10, 11 and 12. Structural causes of dysphagia are considered on page 795. Neurological mechanisms are vulnerable to damage
at different points, resulting in dysphagia that is usually accompanied by dysarthria. Tempo is again crucial: acute onset of dysphagia may occur as a result of brainstem stroke or a rapidly developing neuropathy, such as Guillain–Barre syndrome or diphtheria. Intermittent fatigable muscle weakness (including dysphagia) would suggest myasthenia gravis.

Dysphagia developing over weeks or months may be seen in motor neuron disease, basal meningitis and inflammatory brainstem disease. More slowly developing dysphagia suggests a myopathy or possibly a brainstem or skull-base tumour.

Pathologies affecting lower cranial nerves (9, 10, 11 and 12) frequently manifest bilaterally, producing dysphagia and dysarthria. The term ‘bulbar palsy’ is used to describe lower motor neuron lesions, either within the medulla or outside the brainstem. The tongue may be wasted and fasciculating, and palatal movement is reduced.

Upper motor neuron innervation of swallowing is bilateral, so persistent dysphagia is unusual with a unilateral upper motor lesion (the exception being in the acute stages of, for example, a hemispheric stroke). Widespread lesions above the medulla will cause upper motor neuron bulbar paralysis, known as ‘pseudobulbar palsy’. Here the tongue is small and contracted, and moves slowly; the jaw jerk is brisk, and there may be associated emotional variability. Causes of these are shown in Box 28.22.

Bladder, bowel and sexual disturbance

While isolated disturbances of bladder, bowel and sexual function are rarely the sole presenting features of neurological disease, they are common complications of many chronic disorders such as multiple...
sclerosis, stroke and dementia, and are frequently found post head injury. Abnormalities in these functions considerably reduce quality of life for patients. Incontinence and its management are discussed elsewhere (pp. 567, 833 and 1305).

### Bladder dysfunction

The anatomy and physiology involved in controlling bladder functions are discussed in Chapter 18, but it is worth emphasising the role of the pontine micturition centre, which is itself under higher control via inputs from the pre-frontal cortex, mid-brain and hypothalamus.

In the absence of conscious control (e.g. in coma or dementia), distension of the bladder to near capacity evokes reflex detrusor contraction (analogous to the muscle stretch reflex), and reciprocal changes in sympathetic activation and relaxation of the distal sphincter result in coordinated bladder emptying.

Damage to the lower motor neuron pathways (the pelvic and pudendal nerves) produces a flaccid bladder and sphincter with overflow incontinence, often accompanied by loss of pudendal sensation. Such damage may be due to disease of the conus medullaris or sacral nerve roots, either within the dura (as in inflammatory or carcinomatous meningitis) or as they pass through the sacrum (trauma or malignancy), or due to damage to the nerves themselves in the pelvis (infection, haematoma, trauma or malignancy).

Damage to the pons or spinal cord results in an ‘upper motor neuron’ pattern of bladder dysfunction due to uncontrolled over-activity of the parasympathetic supply. The bladder is small and highly sensitive to being stretched. This results in frequency, urgency and urge incontinence. Loss of the coordinating control of the pontine micturition centre will also result in the phenomenon of detrusor–sphincter dyssynergia, in which detrusor contraction and sphincter relaxation are not coordinated; the spastic bladder will often try to empty against a closed sphincter. This manifests as both urgency and an inability to pass urine, which is distressing and painful. The resultant incomplete bladder emptying predisposes to urinary infection, and the prolonged high intravesical pressure may result in obstructive uropathy and renal failure; post-micturition bladder ultrasound may confirm incomplete bladder emptying. More severe lesions of the spinal cord, as in spinal cord compression or trauma, can result in painless urinary retention as bladder sensation, normally carried in the lateral spinothalamic tracts, will be disrupted.

Damage to the frontal lobes gives rise to loss of awareness of bladder fullness and consequent incontinence. Coexisting cognitive impairment may result in inappropriate micturition. These features may be seen in hydrocephalus, frontal tumours, dementia and bifrontal subdural haematomas.

When a patient presents with bladder symptoms, it is important to localise the lesion on the basis of history and examination, remembering that most bladder problems are not neurological unless there are overt neurological signs. Clinical features and management are summarised in Box 28.23.

### Rectal dysfunction

The rectum has an excitatory cholinergic input from the parasympathetic sacral outflow, and inhibitory sympathetic supply similar to the bladder. Continence depends largely on skeletal muscle contraction in the puborectalis and pelvic floor muscles supplied by the pudendal nerves, as well as the internal and external anal sphincters. Damage to the autonomic components usually causes constipation (a common early symptom in Parkinson's disease) but diabetic neuropathy can be associated with diarrhoea. Lesions affecting the conus medullaris, the somatic S2–4 roots and the pudendal nerves may cause faecal incontinence.

### Erectile failure and ejaculatory failure

These related functions are under autonomic control via the pelvic nerves (parasympathetic, S2–4) and hypogastric nerves (sympathetic, L1–2). Descending influences from the cerebrum are important for erection but it can occur as a reflex phenomenon in response to genital stimulation. Erection is largely parasympathetic and may be impaired by a number of drugs, including anticholinergic, antihypertensive and antidepressant agents. Sympathetic activity is important for ejaculation and may be inhibited by α-adrenoceptor antagonists (α-blockers).

### Personality change

While this is often due to psychiatric illness, neurological conditions that alter the function of the frontal lobes can cause personality change and mood disorder (see Box 28.32). Personality change due to a frontal lobe disorder may occur as the result of structural damage due to stroke, trauma, tumour or hydrocephalus. The nature of any change may help localise the lesion.

Patients with mesial frontal lesions become increasingly withdrawn, unresponsive and mute (abulia), often in association with urinary incontinence, gait apraxia and an increase in tone known as 'gegenhalten' or paratonia, in which the patient varies the resistance to movement in proportion to the force exerted by the examiner.

Patients with lesions of the dorsolateral pre-frontal cortex develop a dysexecutive syndrome, which involves difficulties with speech, motor planning and organisation. Those with orbitofrontal lesions of the frontal lobes, in contrast, become disinhibited, displaying grandiosity or irresponsible behaviour. Memory is substantially intact but frontal release signs may emerge, such as a grasp reflex, palomental response or pout. Proximity to the olfactory bulb and tracts means that inferior frontal lobe turnovers may be associated with anosmia.

Disturbance to the cortical areas responsible for speech or memory can result in changes that may be interpreted as changes in personality.

### Sleep disturbance

Disturbances of sleep are common and are not usually due to neurological disease. Patients may complain of insomnia (difficulty sleeping), excessive daytime sleepiness, disturbed behaviour during night-time sleep, parasomnia (sleep walking and talking, or night terrors) or disturbing subjective experiences during sleep and/or its onset (nightmares, hypnagogic hallucinations, sleep paralysis). A careful history (from bed partner as well as patient) usually allows specific causes of sleep disturbance to be identified and these are discussed in more detail on page 1159.

### Psychiatric disorders

Psychiatric disorders may cause or result from neurological problems. Care is needed in their identification, as effective management will help the underlying neurological illness.

Mood and sleep disturbance will exacerbate neurological symptoms, thus increasing disability. The best practitioners have the skill to carry the patient with them when describing the patterns of behaviour contributing to worsening symptoms.

Assessment to detect an underlying or exacerbating mood disorder is vital in all patients, ensuring that depression and anxiety are managed to minimise their secondary effects on neurological symptoms.

### Headache syndromes

Acute management of headache is dealt with on page 186, but management of chronic, complex, or refractory headaches may require specialist input. Headaches may be classified as primary or secondary, depending on the underlying cause (see Box 9.13). Secondary headache may be due to structural, infective, inflammatory or vascular conditions, discussed later in this chapter. Primary headache syndromes are described here.

### Tension-type headache

This is the most common type of headache and is experienced to some degree by the majority of the population.

**Pathophysiology**

Tension-type headache is incompletely understood, and some consider that it is simply a milder version of migraine; certainly, the original notion
that it is due primarily to muscle tension (hence the unsatisfactory name) has long since been dismissed. Anxiety about the headache itself may lead to continuation of symptoms, and patients may become convinced of a serious underlying condition.

**Clinical features**

The pain of tension headache is characterised as ‘dull’, ‘tight’ or like a ‘pressure’, and there may be a sensation of a band round the head or pressure at the vertex. It is of constant character and generalised, but often radiates forwards from the occipital region. It may be episodic or persistent, although the severity may vary, and there is no associated vomiting or photophobia. Tension-type headache is rarely disabling and patients appear well. The pain often progresses throughout the day. Tenderness may be present over the skull vault or in the occiput but is easily distinguished from the triggered pains of trigeminal neuralgia and the exquisite tenderness of temporal arteritis. Analgesics may be taken with chronic regularity, despite little effect, and may perpetuate the symptoms (see ‘Medication overuse headache’ below).

**Management**

Most benefit is derived from a careful assessment, followed by discussion of likely precipitants and reassurance that the prognosis is good. The concept of medication overuse headache needs careful explanation. An important therapeutic step is to allow patients to realise that their problem has been taken seriously and rigorously assessed. Physiotherapy (with muscle relaxation and stress management) may help and low-dose amitriptyline can provide benefit. Investigation is rarely required. The reassurance value of brain imaging needs careful assessment: the pick-up rate of structural abnormalities is exceedingly low, and significantly outweighed by the likelihood of identifying an incidental and irrelevant finding (e.g. an arachnoid cyst, Chiari I malformation or vascular abnormality). The value of such ‘reassurance’ is usually over-estimated by doctors and patients alike.

**Migraine**

Migraine usually appears before middle age, or occasionally in later life; it affects about 20% of females and 6% of males at some point in life. Migraine is usually readily identifiable from the history, although unusual variants can cause uncertainty.

**Pathophysiology**

The cause of migraine is unknown but there is increasing evidence that the aura (see below) is due to dysfunction of ion channels causing a spreading front of cortical depolarisation (excitation) followed by hyperpolarisation (depression of activity). This process (the ‘spreading depression of Leão’) spreads over the cortex at a rate of about 3 mm/min, corresponding to the aura’s symptomatic spread. The headache phase is associated with vasodilatation of extracranial vessels and may be relayed by hypothalamic activity. Activation of the trigeminovascular system is probably important. A genetic contribution is implied by the frequently positive family history, and similar phenomena occurring in disorders such as CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) or mitochondrial disease (p. 1197). The female preponderance and the frequency of migraine attacks at certain points in the menstrual cycle also suggest hormonal influences. Oestrogen-containing oral contraception sometimes exacerbates migraine and increases the very small risk of stroke in patients who suffer from migraine with aura. Doctors and patients often over-estimate the role of dietary precipitants such as cheese, chocolate or red wine. When psychological factors contribute, the migraine attack often occurs after a period of stress, being more likely on Friday evening at the end of the working week or at the beginning of a holiday.

**Clinical features**

Some patients report a prodrome of malaise, irritability or behavioural change for some hours or days. Around 20% of patients experience an aura and are said to have migraine with aura (previously known as classical migraine). The aura may manifest as almost any neurological symptom but is most often visual, consisting of fortification spectra, which are usually positive phenomena such as shimmering, silvery zigzag lines marching across the visual fields for up to 40 minutes, sometimes leaving a trail of temporary visual field loss (iscotoma). Sensory symptoms characteristically spreading over 20–30 minutes, from one part of the body to another, are more common than motor ones, and language function can be affected, leading to similarities with TIA/stroke. Isolated aura may occur (i.e. the neurological symptoms are not followed by headache).

The 80% of patients with characteristic headache but no ‘aura’ are said to have migraine without aura (previously called ‘common’ migraine).

Migraine headache is usually severe and throbbing, with photophobia, phonophobia and vomiting lasting from 4 to 72 hours. Movement makes the pain worse and patients prefer to lie in a quiet, dark room.

In a small number of patients, the aura may persist, leaving more permanent neurological disturbance. This persistent migraine aura may occur with or without evidence of brain infarction.

**Management**

Avoidance of identified triggers or exacerbating factors (such as the combined contraceptive pill) may prevent attacks. Treatment of an acute attack consists of simple analgesia with aspirin, paracetamol or non-steroidal anti-inflammatory agents. Nausea may require an antiemetic such as metoclopramide or domperidone. Severe attacks can be aborted by one of the ‘triptans’ (e.g. sumatriptan), which are potent 5-hydroxytryptamine (5-HT, serotonin) agonists. These can be administered via the oral, subcutaneous or nasal route. Caution is needed with ergotamine preparations because they may lead to dependence. Overuse of any analgesia, including triptans, may contribute to medication overuse headache.

If attacks are frequent (more than two per month), prophylaxis should be considered. Many drugs can be chosen but the most frequently used are vasoactive drugs (β-adrenoceptor antagonists (β-blockers), candesartan, lisinopril), antidepressants (amitriptyline, doxepin) and antiepileptic drugs (topiramate). Consideration needs to be given to the teratogenicity of antiepileptic drugs in women of childbearing potential. Monoclonal antibodies to calcitonin gene-related peptide receptor are available for refractory migraine. Women with aura should avoid oestrogen treatment for either oral contraception or hormone replacement, although the increased risk of ischaemic stroke is minimal.

**Medication overuse headache**

With increasing availability of over-the-counter medication, headache syndromes perpetuated by analgesia intake are becoming much more common. Medication overuse headache (MOH) can complicate any headache syndrome but is especially common with migraine and chronic tension-type headache. The most frequent culprits are compound analgesics (particularly codeine and other opiate-containing preparations) and triptans, and MOH is usually associated with use on more than 10–15 days per month.

Management is by withdrawal of the responsible analgesics. Patients should be warned that the initial effect will be to exacerbate the headache, and migraine prophylactics may be helpful in reducing the rebound headaches. Relapse rates are high, and patients often need help and support in withdrawing from analgesia; a careful explanation of this paradoxical concept is vital.

**Cluster headache**

Cluster headaches (also known as migrainous neuralgia) are much less common than migraine. Unusually for headache syndromes, there is a significant male predominance and onset is usually in the third decade.

**Pathophysiology**

The cause is unknown but this type of headache differs from migraine in many ways, suggesting a different pathophysiological basis. Although uncommon, it is the most common of the trigeminal autonomic cephalalgia
syndromes. Functional imaging studies have suggested abnormal hypothalamic activity. Patients are more often smokers with a higher than average alcohol consumption.

**Clinical features**

Cluster headache is strikingly periodic, featuring runs of identical headaches beginning at the same time for weeks at a stretch (the ‘cluster’). Patients may experience either one or several attacks within a 24-hour period, and typically are awoken from sleep by symptoms (“alarm clock headache”). Cluster headache causes severe, unilateral periorbital pain with autonomic features, such as ipsilateral tearing, nasal congestion and conjunctival injection (occasionally with the other features of a Horner syndrome). The pain, though severe, is characteristically brief (30–90 minutes). In contrast to the behaviour of those with migraine, patients are highly agitated during the headache phase. The cluster period is typically a few weeks, followed by remission for months to years, but a small proportion do not experience remission.

**Management**

Acute attacks can usually be halted by subcutaneous injections of sumatriptan or inhalation of 100% oxygen. The brevity of the attack probably prevents other migraine therapies from being effective. Migraine prophylaxis is often ineffective too but attacks can be prevented in some patients by verapamil, sodium valproate, or short courses of oral glucocorticoids. Patients with severe debilitating clusters can be helped with lithium therapy, although this requires monitoring.

**Trigeminal neuralgia**

This is characterised by unilateral lancinating facial pain, most commonly involving the second and/or third divisions of the trigeminal nerve territory, usually in patients over the age of 50 years.

**Pathophysiology**

For most, trigeminal neuralgia remains an idiopathic condition but there is a suggestion that it may be due to an irritative lesion involving the trigeminal root zone, in some cases an aberrant loop of artery. Other compressive lesions, usually benign, are occasionally found. Trigeminal neuralgia associated with multiple sclerosis may result from a plaque of demyelination in the brainstem.

**Clinical features**

The pain is repetitive, severe and very brief (seconds or less). It may be triggered by touch, a cold wind or eating. Physical signs are usually absent, although the spasms may make the patient wince and sit silently (tic douloureux). There is a tendency for the condition to remit and relapse over many years. Rarely, there may be combined features of trigeminal neuralgia and cluster headache (‘cluster–tic’).

**Management**

The pain often responds to carbamazepine. It is wise to start with a low dose and increase gradually, according to effect. In patients who cannot tolerate carbamazepine, oxcarbazepine, gabapentin, pregabalin, amitriptyline or glucocorticoids may be effective alternatives, but if medication is ineffective or poorly tolerated, surgical treatment should be considered. Decompression of the vascular loop encroaching on the trigeminal root is often performed and may lead to pain relief in some cases. Otherwise, localised injection of alcohol or phenol into a peripheral branch of the nerve may be effective.

**Headaches associated with specific activities**

These usually affect men in their thirties and forties. Patients develop a sudden, severe headache with exertion, including sexual activity. There is usually no vomiting or neck stiffness, and the headache lasts less than 10–15 minutes, though a less severe dullness may persist for some hours. Subarachnoid haemorrhage needs to be excluded by CT and/or CSF examination (see Fig. 29.13) after a first event. The pathogenesis of these headaches is unknown. Although frightening, attacks are usually brief and patients may need only reassurance and simple analgesia for the residual headache. The syndrome may recur, and prevention may be necessary with propranolol or indomethacin.

**Other headache syndromes**

A number of rare headache syndromes produce pains about the eye similar to cluster headache (Box 28.24). These include chronic paroxysmal hemicrania and SUNCT (short-lasting unilateral neuralgiform headache with conjunctival injection and tearing). The recognition of these syndromes is useful because they often respond to specific treatments such as indomethacin.

*Short-lasting, unilateral, neuralgiform headache with conjunctival injection, tearing, rhinorrhoea and forehead sweating.
Functional neurological disorder

Many patients present with functional symptoms and some may have a functional neurological disorder (FND). FND (also known as functional neurological symptom disorder, dissociative neurological symptom disorder, or conversion disorder) is a disorder at the interface of neurology and psychiatry, reflecting function or dysfunction in the shared organ, the brain. The symptoms are involuntary and cause considerable disability. Core to the assessment and management of most patients is a diagnosis made on positive grounds, communicated to patients in a manner that contributes constructively to management.

Functional symptoms are not consistent with any other recognised neurological disease or disorder. The diagnosis depends on demonstrating internal inconsistency. The inconsistency will depend on the specific functional symptom. Functional symptoms include functional weakness, sensory disturbance, pain, movement disorders, dissociative attacks (also called non-epileptic attacks), visual symptoms, speech and cognitive symptoms. Examples of internal inconsistency include: weakness of hip extension when the patient tries to extend the hip, which is overcome when the opposite hip is flexed against resistance (Hoover’s sign); marked weakness of the legs on examination in a patient able to stand and walk; a detailed description of specific events of memory loss; and expressive dysphasia with retained written language. Other findings may include: non-anatomical sensory loss, abnormal movements that are distractable, and dissociative or non-epileptic attacks occurring in the absence of concomitant EEG abnormality. Tiredness, poor concentration and sleep disturbance are also common.

Many but not all patients with FND have predisposing factors (Box 28.25) that may include anxiety, depression, post-traumatic stress disorder, a history of abuse or aversive events. There may be a precipitating event, which may at times appear minor in comparison to the range and severity of the patient’s symptoms.

The approach to the patient with FND or functional symptoms should ideally include:

- a detailed history exploring all symptoms
- examination looking for positive findings, e.g. Hoover’s sign
- review of past medical records, which often contain functional symptoms in other organ systems, e.g. irritable bowel syndrome, globus, non-cardiac chest pain
- rapid investigation to exclude a structural cause
- and a clear, constructive explanation of the diagnosis based on positive findings rather than the rather unhelpful ‘medically unexplained symptom’ approach of the past.

There are several useful websites that provide patients with additional information and advice (p. 100). For many patients understanding their symptoms and the condition will be sufficient, others may require additional multidisciplinary support and treatment from a range of professionals including: physiotherapy, occupational and speech therapy, neurology and neuropsychiatry/psychiatry. Treatment may include neurophysiotherapy, use of antidepressant medication (although not all patients are depressed) and cognitive behavioural therapy. The diagnosis should not be made simply because the patient’s presentation is unusual. A diagnosis of FND should be based on an appropriate history, examination and normal relevant findings on investigation.

Factitious disorders and malingering are not the same as FND. In the absence of clear objective evidence, e.g. witnessing a patient tampering with tests, diagnosis of these disorders should best be left to psychiatrists.

Epilepsy

A seizure can be defined as the occurrence of signs and/or symptoms due to abnormal, excessive or synchronous neuronal activity in the brain. The lifetime risk of an isolated seizure is about 5%, although incidence is highest at the extremes of age. Epilepsy is the tendency to have unprovoked seizures. While the prevalence of active epilepsy in European countries is about 0.5%, this figure varies globally and can be influenced by the prevalence of parasitic illnesses such as cysticercosis. A recent change in definition allows the diagnosis of epilepsy to be made after a single seizure with a high risk of recurrence (e.g. a single seizure in the presence of a cortical lesion). Such changes may lead to an observed increase in epilepsy incidence.

Historical terms such as ‘grand mal’ (implying tonic–clonic seizures) and ‘petit mal’ (intended originally to mean ‘absence seizures’ but commonly misused to describe ‘anything other than grand mal’) have been superseded. Subsequent revisions, including terms such as ‘complex partial’ and ‘simple partial’, have been imprecise and carry little information about underlying pathology, treatment or prognosis. The modern equivalents for these terms will be given below, but it is preferable to adhere to the 2017 iteration of the International League Against Epilepsy’s classification (Box 28.26).

Pathophysiology

To function normally, the brain must maintain a continual balance between excitation and inhibition, remaining responsive to the environment while avoiding continued unrestrained spontaneous activity. The inhibitory transmitter gamma-aminobutyric acid (GABA) is particularly important, acting on ion channels to enhance chloride inflow and reducing the chances of action potential formation. Excitatory amino acids (glutamate and aspartate) allow influx of sodium and calcium, producing the opposite effect. It is likely that many seizures result from an imbalance between this excitation and inhibition. Intracellular recordings during seizures demonstrate a paroxysmal depolarisation shift in neuronal membrane potential, an upshift in internal potential predisposing to recurrent action potentials. In vivo, epileptic cortex shows repetitive discharges involving large groups of neurons.

Focal epilepsy

Seizures may be related to a localised disturbance in the cortex, becoming manifest in the first instance as focal seizures. Any disturbance of cortical architecture and function can precipitate this, whether focal infection, tumour, hamartoma or trauma-related scarring. If focal seizures remain localised, the symptoms experienced depend on which cortical area is affected. If areas in the temporal lobes become involved, then awareness of the environment becomes impaired but without associated tonic–clonic movements. When both hemispheres become involved, the seizure becomes generalised (Fig. 28.23).

Generalised epilepsies

The new terminology is genetic generalised epilepsies (GGEs) (previously idiopathic generalised epilepsies, and many prefer to still use this term) to reflect their likely cause. These seizures are generalised at onset, abnormal activity probably originating in the central mechanisms controlling cortical activation (see Fig. 28.23) and spreading rapidly. This group constitutes around 30% of all epilepsy and is likely to reflect widespread
Generalised onset

Motor
- Tonic–clonic (in any combination)
- Clonic
- Tonic
- Myoclonic
- Myoclonic–tonic–clonic
- Myotonic–atonic
- Atonic
- Epileptic spasms

Non-motor (absence):
- Typical
- Atypical
- Myoclonic
- Eyelid myoclonia

Focal onset

(Can occur with retained awareness or impaired awareness)

Motor onset
- Automatisms
- Atonic
- Clonic
- Epileptic spasms
- Hyperkinetic
- Myoclonic
- Tonic

Nonmotor onset
- Autonomic
- Behaviour arrest
- Cognitive
- Emotional
- Sensory

Focal to bilateral tonic–clonic

Unknown onset

Motor
- Tonic–clonic
- Epileptic spasms

Non-motor
- Behavioural arrest

---

**Fig. 28.23** The pathophysiological classification of seizures. **A** A focal seizure originates from a paroxysmal discharge in a focal area of the cerebral cortex (often the temporal lobe); the seizure may subsequently spread to the rest of the brain (secondary generalisation) via diencephalic activating pathways. **B** In genetic generalised epilepsies (GGEs) the abnormal electrical discharges originate from the diencephalic activating system and spread simultaneously to all areas of the cortex.

---

**28.26 Classification of seizures (2017 International League Against Epilepsy classification)**

**28.27 Trigger factors for seizures**

- Sleep deprivation
- Missed doses of antiepileptic drugs in treated patients
- Alcohol (particularly withdrawal)
- Recreational drug misuse
- Physical and mental exhaustion
- Flickering lights, including TV and computer screens (generalised epilepsy syndromes only)
- Intercurrent infections and metabolic disturbances
- Uncommon: loud noises, music, reading, hot baths

---

Disturbance of structure or function. GGEs almost always become apparent before the age of 35.

Seizure activity is usually apparent on EEG as spike and wave discharges (see Fig. 28.14). Other generalised seizures may involve merely brief loss of awareness (absence seizures), single jerks (myoclonus) or loss of tone (atonic seizures), as detailed in **Box 28.26**.

---

**Clinical features**

**Seizure type and epilepsy type**

Patients can experience more than one type of seizure attack, and it is important to document each attack type and the patient’s age at its onset, along with its frequency, duration and typical features. Any triggers should be identified (**Box 28.27**). The type of seizure, other clinical features and investigations can then be used to determine the epilepsy syndrome, as discussed below. Where there is doubt about the type, this is best stated and a full classification should be deferred until the evolution of the clinical features clarifies the picture.

To classify seizure type, the clinician should ask firstly whether there is a focal onset, and secondly whether the seizures conform to one of the recognised patterns (see **Box 28.26**). Epilepsy that starts in patients beyond their mid-thirties will almost invariably reflect a focal cerebral event. Where activity remains focal, the classification will be obvious. With generalised tonic–clonic seizures, a focal onset will be heralded by positive neurological symptoms and signs corresponding to the normal function of that area. Occipital onset causes visual changes (lights and blobs of colour), temporal lobe onset causes false recognition (déjà vu), sensory strip involvement causes sensory alteration (burning, tingling) and motor strip involvement causes jerking.

Alternatively, patients report a previous local cortical insult, and it may be reasonably (but not invariably) inferred that this is the seat of epileptogenesis.

**Focal seizures**

The classification of focal seizures is shown in **Box 28.26**. They are caused by localised cortical activity. The localisation of such symptoms is described above. A spreading pattern of seizure may occur, the abnormal sensation spreading much faster (in seconds) than a migrainous focal sensory attack.

Awareness may become impaired if spread occurs to the temporal lobes (previously ‘complex partial seizure’). Patients stop and stare blankly, often blinking repetitively, making smacking movements of their lips or displaying other automatisms, such as picking at their clothes. After a few minutes consciousness returns but the patient may be muddled and feel drowsy for a period of up to an hour. The age of onset, preceding aura, longer duration and post-ictal symptoms usually make these easy to differentiate from childhood absence seizures (see below).

Seizures arising from the anterior parts of the frontal lobe may produce bizarre behavioural patterns, including limb posturing, sleep walking or even frenetic, ill-directed motor activity with incoherent screaming. Vagal EEG may be necessary to differentiate these from psychogenic attacks (which are more common) but abruptness of onset, stereotyped nature, relative brevity and nocturnal preponderance may indicate a frontal origin. Causes of focal seizures are given in **Box 28.28**.
### 28.28 Causes of focal seizures

**Idiopathic**
- Benign Rolandic epilepsy of childhood
- Benign occipital epilepsy of childhood

**Focal structural lesions**
- Tuberous sclerosis
- Autosomal dominant nocturnal frontal lobe epilepsy
- Autosomal dominant partial epilepsy with auditory features (ADPEAF)

**Genetic**
- von Hippel–Lindau disease
- Neurofibromatosis
- Cerebral migration abnormalities

**Infantile hemiplegia**
- Cortical dysgenesis

**Mesial temporal sclerosis (associated with febrile convulsions)**
- Intracerebral haemorrhage
- Cerebral infarction

**Cerebrovascular disease (see Ch. 29)**
- Subdural empyema
- Encephalitis
- Human immunodeficiency virus (HIV)

**Inflammatory**
- Autoimmune encephalopathies (e.g. anti-voltage-gated potassium channel antibodies, anti-NMDA receptor antibodies)
- Sarcoïdosis
- Vasculitis

### 28.29 Causes of generalised tonic–clonic seizures

**Generalisation from focal seizures**
- See Box 28.28

**Genetic**
- Inborn errors of metabolism
- Storage diseases

**Cerebral birth injury**
- Hydrocephalus
- Cerebral anoxia

**Drugs**
- Antibiotics: penicillin, isoniazid, metronidazole
- Antimalarials: chloroquine, mefloquine
- Cicloserin
- Antidepressants: (withdrawal)

**Alcohol (especially withdrawal)**
- Organophosphates (sarin)

**Toxins**
- Heavy metals (lead, tin)

**Metabolic disease**
- Hypocalcaemia
- Hypophosphataemia
- Hypomagnesaemia

**Infective**
- Post-infectious encephalopathy

**Inflammatory**
- Multiple sclerosis (uncommon)

**Diffuse degenerative diseases**
- Alzheimer’s disease (uncommonly)
- Creutzfeldt–Jakob disease (rarely)

**Atonic seizures** These are seizures involving brief loss of muscle tone, usually resulting in head falls with or without loss of consciousness. They occur only in the context of epilepsy syndromes that involve other forms of seizure.

**Tonic seizures** These are associated with a generalised increase in tone and an associated loss of awareness. They are usually seen as part of an epilepsy syndrome and are unlikely to be isolated.

**Clonic seizures** Clonic seizures are similar to tonic–clonic seizures. The clinical manifestations are similar but there is no preceding tonic phase.

**Seizures of uncertain generalised or focal nature**

**Epileptic spasms** While these are highlighted in the classification system, they are unusual in adult practice and occur mainly in infancy. They signify widespread cortical disturbance and take the form of marked contractions of the axial musculature, lasting a fraction of a second but recurring in clusters of 5–50, often on awakening.

### Epilepsy syndromes

Many patients with epilepsy fall into specific patterns, depending on seizure type(s), age of onset and treatment responsiveness: the so-called electroclinical syndromes (Box 28.30). It is anticipated that genetic testing will ultimately demonstrate similarities in molecular pathophysiology.

Box 28.31 highlights the more common epilepsy syndromes, which are largely of early onset and are sensitive to sleep deprivation, hyperventilation, alcohol and photic stimulation. Epilepsies that do not fit into any of these diagnostic categories can be delineated firstly on the basis
of the presence or absence of a known structural or metabolic condition (presumed cause), and then on the basis of the primary mode of seizure onset (generalised versus focal).

### Investigations

#### Single seizure

All patients with transient loss of consciousness should have a 12-lead ECG. Where seizure is suspected or definite, patients should have cranial imaging with either MRI or CT, although the yield is low unless focal signs are present. EEG may help to assess prognosis once a firm diagnosis has been made. The recurrence rate after a first seizure is approximately 40% and most recurrent attacks occur within a month or two of the first. Further seizures are less likely if an identified trigger can be avoided (see Box 28.27).

Other investigations for infective, toxic and metabolic causes (Box 28.32) may be appropriate. An EEG performed immediately after a seizure may be more helpful in showing focal features than if performed after a delay.

### Epilepsy

The same investigations are required in a patient with epilepsy (Box 28.32). The EEG may help to establish the type of epilepsy and guide therapy. Investigations should be revisited if the epilepsy is intractable to treatment.

Inter-ictal EEG is abnormal in only about 50% of patients with recurrent seizures, so it cannot be used to exclude epilepsy. The sensitivity can be increased to about 85% by prolonging recording time and including a period of normal or drug-induced sleep, but this does not replace a well-taken history. Ambulatory EEG recording or video EEG monitoring may help with differentiation of epilepsy from other disorders if attacks are sufficiently frequent.

### Common generalised epilepsy syndromes

<td>GTCS, sometimes myoclonus</td>
<td>Spike and wave on waking and sleep onset</td>
<td>Sodium valproate Levetiracetam</td>
<td>65% controlled with AEDs but relapse off treatment</td>
</tr>
</tbody>
</table>

(AED = antiepileptic drug; GTCS = generalised tonic–clonic seizure)
**28.33 Indications for brain imaging in epilepsy**

- Epilepsy starting after the age of 16 years
- Seizures having focal features clinically
- Electroencephalogram showing a focal seizure source
- Control of seizures difficult or deteriorating

**28.34 How to administer first aid for seizures**

- Move the person away from danger (fire, water, machinery, furniture)
- After convulsions cease, turn the person into the ‘recovery’ position (semi-prone)
- Ensure the airway is clear but do **NOT** insert anything in the mouth (tongue-biting occurs at seizure onset and cannot be prevented by observers)
- If convulsions continue for more than 5 mins or recur without the person regaining consciousness, summon urgent medical attention
- Do not leave the person alone until fully recovered (drowsiness and delirium can persist for up to 1 hr)

**28.35 Epilepsy: outcome after 20 years**

- 50% are seizure-free, without drugs, for the previous 5 years
- 20% are seizure-free for the previous 5 years but continue to take medication
- 30% continue to have seizures in spite of antiepileptic therapy

Indications for imaging are summarised in Box 28.33. Imaging cannot establish a diagnosis of epilepsy but identifies any structural cause. It is not required if a confident diagnosis of a recognised GGE syndrome (e.g. juvenile myoclonic epilepsy) is made. While CT excludes a major structural cause of epilepsy, MRI is required to demonstrate subtle changes such as hippocampal sclerosis, which may direct or inform surgical intervention.

### Management

It is important to explain the nature and cause of seizures to patients and their relatives, and to instruct relatives in the first aid management of seizures (Box 28.34). Many people with epilepsy feel stigmatised and may become unnecessarily isolated from work and social life. It is important to emphasise that epilepsy is a common disorder that affects 0.5%–1% of the population, and that full control of seizures can be expected in approximately 70% of patients (Box 28.35).

**Immediate care**

Little can or needs to be done for a person during a convulsive seizure except for first aid and common-sense manoeuvres to limit damage or secondary complications (see Box 28.34). Advice should be given that on no account should anything be inserted into the patient’s mouth. The management of status epilepticus is described on page 1137.

**Lifestyle advice**

Patients should be advised to avoid activities where they might place themselves or others at risk if they have a seizure. This applies at work, at home and at leisure. At home, only shallow baths (or showers) should be taken. Prolonged cycle journeys should be discouraged until reasonable freedom from seizures has been achieved. Activities involving prolonged proximity to water (swimming, fishing or boating) should always be carried out in the company of someone who is aware of the risks and the potential need for rescue measures. Driving regulations vary between countries and the patient should be made aware of these (Box 28.36). Certain occupations, such as firefighter or airline pilot, are not open to those with a previous or active diagnosis of epilepsy; further information is available from epilepsy support organisations.

The risk of harm from epilepsy should be discussed around the time of diagnosis. In particular epilepsy is associated with a very small, but potentially modifiable, risk of sudden death (sudden unexpected death in epilepsy, SUDEP). Explaining risks of epilepsy, including SUDEP, should be done with care and sensitivity, and with the aim of motivating the patient to adapt habits and lifestyle to optimise epilepsy control and minimise risks of serious complications.

**Antiepileptic drugs**

Antiepileptic drugs (AEDs) should be considered where risk of seizure recurrence is high. A diagnosis of two or more seizures is justification enough but a prolonged inter-seizure interval may deter some patients and physicians. Treatment decisions should always be shared with the patient, to enhance adherence. A wide range of drugs is available. These agents either increase inhibitory neurotransmission in the brain or alter neuronal sodium channels to prevent abnormally rapid transmission of impulses. In the majority of patients, full control is achieved with a single drug. Dose regimens should be kept as simple as possible. Guidelines are listed in Box 28.37. For focal epilepsies, one large study suggests that lamotrigine is the best-tolerated monotherapy, which, alongside its favourable adverse-effect profile and relative lack of pharmacokinetic interactions, makes it a good first-line drug, although caution must be exercised with oral contraceptive use. Unclassified or genetic generalised epilepsies respond best to valproate, although pregnancy-related problems mean that valproate should not be used in women of reproductive age unless the benefits outweigh the risks. The initial choice should be an established first-line drug (Box 28.38), with more recently introduced drugs as second choice.

**Monitoring therapy**

Some practitioners confuse epilepsy care with serum level monitoring. The newer drugs have much more predictable pharmacokinetics than the older ones and the only indication for measuring serum levels is if there is doubt about adherence. Blood levels need to be interpreted carefully and dose changes made to treat the patient rather than to bring a serum level into the “therapeutic range”. Some centres advocate serum level monitoring during pregnancy (notably with lamotrigine) but the evidence of benefit for this is not strong.
Epilepsy surgery

Some patients with drug-resistant epilepsy benefit from surgical resection of epileptogenic brain tissue. Less invasive treatments, including vagal nerve stimulation or deep brain stimulation, may also be helpful in some patients. All those who continue to experience seizures despite appropriate drug treatment should be considered for surgical treatment. Planning such interventions requires intensive specialist assessment and investigation to identify the site of seizure onset and the dispensability of any target areas for resection, i.e. whether the area of brain involved is necessary for a critical function such as vision or motor function.

Withdrawing antiepileptic therapy

Withdrawal of medication may be considered after a patient has been seizure-free for more than 2 years. Childhood-onset epilepsy, particularly classical absence seizures, carries the best prognosis for successful drug withdrawal. Other epilepsy syndromes, such as juvenile myoclonic epilepsy, have a marked tendency to recur after drug withdrawal.

Focal epilepsies that begin in adult life are also likely to recur, especially if there is an identified structural lesion. Overall, the recurrence rate after drug withdrawal depends on the individual’s epilepsy history. An individualised estimate may be gained from the SIGN guideline tables (see “Further information”).

Patients should be advised of the risks of recurrence, to allow them to decide whether or not they wish to withdraw. If undertaken, withdrawal should be done slowly, reducing the drug dose gradually over weeks or months. Withdrawal may necessitate precautions around driving or occupation (see Box 28.36).

Contraception

Some AEDs induce hepatic enzymes that metabolise synthetic hormones, increasing the risk of contraceptive failure. This is most marked with carbamazepine, phenytoin and barbiturates, but clinically significant effects can be seen with lamotrigine and topiramate. If the AED cannot be changed, this can be overcome by giving higher-dose preparations of the oral contraceptive. Sodium valproate and levetiracetam have no interaction with hormonal contraception.

Pregnancy and reproduction

Epilepsy presents specific management problems during pregnancy (Box 28.39). There is usually concern about the risks of teratogenesis associated with AEDs which must be balanced against the benefits of these drugs. It is important to recognise proportionate risks: background risk of severe fetal malformation in the general population is around 2%–3%, while the AED most associated with teratogenesis is sodium valproate, which, at high dose, increases the risk to up to 10%. Long-term observational studies show that most of the commonly used AEDs can be given safely in pregnancy, although the risk of congenital abnormalities in the fetus is dependent on the type, number and dose of AEDs.

Over the past few years medicines regulatory agencies have strengthened their warnings surrounding the risk of birth defects and developmental disorders in children born to women who take valproate during pregnancy. In the UK it has been emphasised that if valproate is taken during pregnancy, up to 4 in 10 babies are at risk of developmental disorders, in addition to the 1 in 10 who are at risk of birth defects. Consequently, in the UK, valproate must no longer be used in any woman or girl able to have children, unless she has a pregnancy prevention programme in place.

Pre-conception treatment with folic acid (5mg daily), along with use of the smallest effective doses of as few AEDs as possible, may reduce the risk of fetal abnormalities. The risks of abrupt AED withdrawal to the mother should be stressed.

Seizures may become more frequent during pregnancy, particularly if pharmacokinetic changes decrease serum levels of AEDs (see Box 28.39).

Menstrual irregularities and reduced fertility are more common in women with epilepsy, and are also increased by sodium valproate. Patients with epilepsy are at greater risk of osteoporosis, apparently independently of the drug used. Some centres advocate vitamin D supplementation in any patient with epilepsy but the higher female risk of osteoporosis makes this most important in women. Oral contraception can interact with individual AEDs (see Box 28.39).

Prognosis

The outcome of newly diagnosed epilepsy is generally good. Overall, generalised epilepsies and generalised seizures are more readily controlled than focal seizures. The presence of a structural lesion reduces the chances of freedom from seizures. The overall prognosis for
28.39 Epilepsy in pregnancy

- **Provision of pre-conception counselling is best practice**: start folic acid (5 mg daily for 2 months) before conception to reduce the risk of fetal malformations.
- **Fetal malformation**: risk is minimised if a single drug is used. Carbamazepine and lamotrigine have the lowest incidence of major fetal malformations. The risk with sodium valproate is particularly high (see text) and should be carefully balanced against its benefits.
- **Levetiracetam**: may be safe but avoid other newer drugs if possible.
- **Learning difficulties in children**: IQ may be lower when children are exposed to valproate in utero, so its use should always be considered carefully.
- **Haemorrhagic disease of the newborn**: enzyme-inducing antiepileptic drugs increase risk. Give IM vitamin K (1 mg) to the infant at birth.
- **Increased frequency of seizures**: where breakthrough seizures occur, monitor antiepileptic drug levels and adjust the dose regimen accordingly.
- **Pharmacokinetic effects of pregnancy**: carbamazepine levels may fall in the third trimester. Lamotrigine and levetiracetam levels may fall early in pregnancy. Some advocate monitoring of levels.

28.40 Epilepsy in old age

- **Incidence and prevalence**: late-onset epilepsy is very common and the annual incidence in those over 60 years is rising.
- **Fits and fants**: the features that usually differentiate these may be less definitive than in younger patients.
- **Non-convulsive status epilepticus**: can present as delirium in old age.
- **Cerebrovascular disease**: the underlying cause of seizures in 30%–50% of patients over the age of 50 years. A seizure may occur with an overt stroke or with occult vascular disease.
- **Neurogenerative disease or dementia**: should be considered when epilepsy presents in old age.
- **Antiepileptic drug regimens**: keep as simple as possible and take care to avoid interactions with other drugs being prescribed.
- **Carbamazepine-induced hyponatraemia**: increases significantly with age; this is particularly important in patients on diuretics or those with heart failure.
- **Withdrawal of antiepileptic therapy**: drug withdrawal should be attempted only where benefits exceed risk of harm from seizures.

28.41 Epilepsy in adolescence

- **Effect on school/education**: seizures, antiepileptic drugs (AEDs) and psychological complications of epilepsy may hamper education. Fear may make some educational institutions unduly restrictive.
- **Effect on family relationships**: parents may adopt a protective role, which can lead to epilepsy (and AEDs) becoming a point of assertion and rebellion.
- **Effect on career choice**: epilepsy may exclude or restrict employment in the emergency services and armed forces.
- **Alcohol**: may affect sleep pattern; excess may be associated with poor AED adherence.
- **Illicit drugs**: may affect seizure threshold and be associated with poor AED adherence.
- **Sleep disturbance**: may be worsened by social activities and computer games.
- **Oral contraception**: interactions with AED can occur. Use may not always be disclosed to parents.

Epilepsy is shown in Box 28.35. Problems that epilepsy poses in older adults and in adolescents are summarised in Boxes 28.40 and 28.41, respectively.

**Status epilepticus**

Presentation and management are described on page 1137. While generalised status epilepticus is most easily recognised, non-convulsive status may be less dramatic and less easily diagnosed. It may cause only altered awareness, delirium or wandering with automatisms. In an intensive care unit setting, EEG monitoring is essential to ensure that diagnosis and treatment are optimised.

**Non-epileptic attack disorder (‘dissociative attacks’)**

The difficulty with nomenclature is discussed on page 1152. Patients may present with attacks that resemble epileptic seizures but are caused by psychological phenomena and have no abnormal EEG discharges. Such attacks may be very prolonged, sometimes mimicking status epilepticus. Epileptic and non-epileptic attacks may coexist and time and effort are needed to clarify the relative contribution of each, allowing more accurate and comprehensive treatment.

Non-epileptic attack disorder (NEAD) may be accompanied by dramatic flailing of the limbs and arching of the back, with side-to-side head movements and vocalising. Cyanosis and severe biting of the tongue are rare but incontinence can occur. Distress and crying are common following non-epileptic attacks. The distinction between epileptic attacks originating in the frontal lobes and non-epileptic attacks may be especially difficult, and may require videotelemetry with prolonged EEG recordings. Non-epileptic attacks are three times more common in women than in men. They are not necessarily associated with formal psychiatric illness. Patients and carers may need reassurance that hospital admission is not required for every attack. Prevention requires psychotherapeutic interventions rather than drug therapy.

**Vestibular disorders**

Vertigo is the typical symptom caused by vestibular dysfunction, and most patients with vertigo have acute vestibular failure, benign paroxysmal positional vertigo or Ménière’s disease. Central (brain) causes of vertigo are rare by comparison, with the exception of migraine.

**Acute vestibular failure**

Although commonly called ‘labyrinthitis’ or ‘vestibular neuritis’, acute vestibular failure is a more accurate term, as most cases are idiopathic. It usually presents as isolated severe vertigo with vomiting and unsteadiness. It begins abruptly, often on waking, and many patients are initially bed-bound. The vertigo settles within a few days, though head movement may continue to provoke transient symptoms (positional vertigo) for some time. During the acute attack, nystagmus will be present for a few days.

Cinnarizine, prochlorperazine or betahistine provide symptomatic relief but should not be used long term, as this may delay recovery. A small proportion of patients fail to recover fully and complain of ongoing imbalance and dysequilibrium rather than vertigo; vestibular rehabilitation by a physiotherapist may help.

**Benign paroxysmal positional vertigo**

Benign paroxysmal positional vertigo (BPPV) is due to the presence of otolithic debris from the saccule or utricle affecting the free flow of endolymph in the semicircular canals (cupulolithiasis). It may follow minor head injury but typically is spontaneous. The history is diagnostic, with transient (seconds) vertigo precipitated by movement (typically, rolling over in bed or getting into or out of bed). Although it is benign, and usually self-limiting after weeks or months, patients are often alarmed by the symptoms. The diagnosis can be confirmed by the “Hallpike manoeuvre” to demonstrate positional nystagmus (Fig. 28.24). Treatment comprises explanation and reassurance, along with positioning procedures designed to return otolithic debris from the semicircular canal to saccule or utricle (such as the Epley manoeuvre) and/or re-educate the brain to cope with the inappropriate signals from the labyrinth (such as Cawthorne–Cooksey exercises: see ‘Further information’).
Ménière disease

This is due to an abnormality of the endolymph that causes episodes of vertigo accompanied by tinnitus and fullness in the ear, each attack typically lasting a few hours. Over the years, patients may develop progressive deafness (typically low-tone on audiometry). Examination is typically normal in between attacks. The diagnosis is clinical, supported by abnormal audiometry. Ménière disease is idiopathic but a similar syndrome may be caused by middle ear trauma or infection. Imaging may be indicated to exclude other focal brainstem or cerebellopontine angle pathology but will be normal in Ménière disease. Management includes a low-salt diet, vestibular sedatives for acute attacks (e.g. cinnarizine or prochlorperazine), and occasionally surgery to increase endolymphatic drainage from the vestibular system. Migraine may also cause episodic vertigo, and can be confused with Ménière disease, although usually other migrainous features will appear in the history.

Disorders of sleep

Sleep disturbances include too much sleep (hypersomnolence or excessive daytime sleepiness), insufficient or poor-quality sleep (insomnia) and abnormal behaviour during sleep (parasomnias). Insomnia is usually caused by psychological or psychiatric disorders, shift work and other environmental causes, pain and so on, and will not be discussed further. Many symptoms and disorders may affect sleep and sleep quality (e.g. pain, depression/anxiety, parkinsonism).

Excessive daytime sleepiness (hypersomnolence)

There are primary and secondary causes (Box 28.42). The most common causes are impaired sleep due to lifestyle issues or sleep-disordered breathing. Sleepiness may be measured using the Epworth sleepiness scale (see Box 17.86). Most causes will be identified by a detailed history from the patient and their bed partner, and a 2-week sleep diary.

Narcolepsy

This has a prevalence of about 1 in 2000, with peak onset in adolescence and early middle age. The key symptom is sudden, irresistible ‘sleep attacks’, often in inappropriate circumstances such as while eating or talking. Other characteristic features help distinguish this from excessive daytime sleepiness (Box 28.43). Symptoms may be due to loss of hypocretin-secreting hypothalamic neurons. Diagnosis requires sleep study with sleep latency testing (demonstrating rapid onset of REM sleep). Narcolepsy may respond to stimulants such as modafinil but more severe cases may require sodium oxybate, dexamfetamine, methylphenidate or a selective serotonin reuptake inhibitor (SSRI). Cataplexy can be debilitating and can respond to sodium oxybate or to antidepressants, such as clomipramine or venlafaxine.

Parasomnias

Parasomnias are abnormal motor behaviours that occur around sleep. They may arise in either REM or non-REM sleep, with characteristic

28.43 Narcolepsy symptoms

**Sleep attacks**

- Brief, frequent and unlike normal somnolence
- Cataplexy
  - Sudden loss of muscle tone triggered by surprise, laughter, strong emotion etc.
- Hypnagogic or hypnopompic hallucinations
  - Frightening hallucinations experienced during sleep onset or waking due to intrusion of REM sleep during wakefulness (can occur in normal people)

**Sleep paralysis**

- Brief paralysis on waking (can occur in normal people)

Fig. 28.24 The Halipke manoeuvre for diagnosis of benign paroxysmal positional vertigo (BPPV). Patients are asked to keep their eyes open and look at the examiner as their head is swung briskly backwards through 120° to overhang the edge of the couch. A Perform first with the right ear down. B Perform next with the left ear down. The examiner looks for nystagmus (usually accompanied by vertigo). In BPPV, the nystagmus typically occurs in A or B only and is torsional, the fast phase beating towards the lower ear. Its onset is usually delayed a few seconds and it lasts 10–20 seconds. As the patient is returned to the upright position, transient nystagmus may occur in the opposite direction. Both nystagmus and vertigo typically decrease (fatigue) on repeat testing.
features and timing. Non-REM parasomnias tend to occur early in sleep. Parasomnias should be distinguished from other motor disturbances (such as periodic limb movements, hypnic jerks or sleep talking) and sleep-onset epileptic seizures. History from a sleeping partner or other witness is essential.

Non-REM parasomnias

These are due to incomplete arousal from non-REM sleep and manifest as night terrors, sleep walking and confusional arousals (sleep drunkenness). They typically occur within an hour or two of sleep onset, are common in children and usually of no pathological significance. Rarely, they persist into adulthood and may become increasingly complex, including dressing, moving objects, eating, drinking or even acts of violence. Patients have little or no recollection of the episodes, even though they appear ‘awake’. The episodes may be triggered by alcohol or unfamiliar sleeping situations and can be familial. Treatment is usually not required but clonazepam can be used.

REM sleep behaviour disorder

In REM sleep behaviour disorder (RBD), patients ‘act out’ their dreams during REM sleep, due to failure of the usual muscle atonia. Sleep partners provide typical histories of patients ‘fighting’ or ‘struggling’ in their sleep, sometimes causing injury to themselves or to their partner. They are easily roused from this state, with recollection of their dream, unlike in non-REM states. RBD is more common in men and may be an early symptom of neurodegenerative diseases such as alpha synucleinopathies, perhaps preceding more typical symptoms of these conditions by years. Polysomnography will confirm absence of atonia during REM sleep. Clonazepam is the most successful treatment.

Restless legs syndrome

Restless legs syndrome (RLS) is common, with a prevalence of up to 10%, but many patients never seek medical attention. It is characterised by unpleasant leg (rarely, arm) sensations that are eased by movement (motor restlessness); the diagnosis is clinical (Box 28.44). It has a strong familial tendency and can present with daytime somnolence due to poor sleep. It is usually idiopathic but may be associated with iron deficiency, pregnancy, peripheral neuropathy, Parkinson’s disease or unamnia. It should be distinguished from akathisia, the daytime motor restlessness that is an adverse effect of antipsychotic drugs. Treatment, if required, is with gabapentanoids, dopaminergic drugs (dopamine agonists or levodopa) or benzodiazepines. Serum ferritin should be maintained above 75μg/L.

Periodic limb movements in sleep

Unlike RLS, periodic limb movements in sleep (PLMS) only occur during sleep and cause repetitive flexion movements of the limbs, usually in the early (non-REM) stages of sleep. Although patients are unaware of the symptoms, they may disrupt sleep quality and often disturb partners. The pathological significance of PLMS is uncertain and it often occurs in normal health. There is an overlap with RLS. Treatment is most successful with clonazepam or dopaminergic drugs.

Neuro-inflammatory diseases

Multiple sclerosis

Multiple sclerosis (MS) is an important treatable cause of long-term disability in adults. The annual incidence is around 7 per 100,000, while the lifetime risk of developing MS is about 1 in 400. The incidence of MS is higher in Northern Europeans and the disease is about twice as common in females.

Pathophysiology

There is evidence that both genetic and environmental factors play a causal role. The prevalence of MS is low near the equator and increases in the temperate zones of both hemispheres. People retain the risk of developing the disease in the zone in which they grew up, indicating that environmental exposures during growth and development are important. Prevalence also correlates with environmental factors, such as sunlight exposure, vitamin D and exposure to Epstein–Barr virus (EBV), although causative mechanisms remain unclear. Genetic factors are also relevant; the risk of familial occurrence in MS is 15%, with highest risk in first-degree relatives (age-adjusted risk 4%–5% for siblings and 2%–3% for parents or offspring). Large genome-wide association studies (GWAS) of MS implicate the modest influence of hundreds of genes, in particular those with an immunological function, and there is overlap with other immune diseases. An autoimmune cause of multiple sclerosis is therefore supported by genetic studies, a prominent role of immune cells in disease pathogenesis and efficacy of multiple immune therapies.

Initial CNS inflammation in MS involves entry of lymphocytes across the blood–brain barrier, which can be inhibited by monoclonal antibodies like natalizumab which bind α4β1-integrin. These cells proliferate in perivascular lesions and the resulting inflammatory cascade releases cytokines and initiates destruction of the oligodendrocyte–myelin unit. Histologically, the resultant lesion is a plaque of inflammatory demyelination, most commonly in the periventricular regions of the brain, the optic nerves and the spinal cord (Fig. 28.25), and also found in the cortex. After the acute attack, gliosis and repair by oligodendrocyte precursor cells follows, leaving a shrunken scar.

Much of the initial acute clinical deficit is caused by the effect of inflammation on transmission of the nervous impulse rather than structural disruption of myelin, and may explain the rapid recovery of some deficits. In the long term, accumulating myelin loss reduces the efficiency of impulse propagation or causes complete conduction block, contributing to sustained impairment of CNS functions. Inflammatory mediators released during the acute attack, and loss of structural and trophic support from myelinating cells, contribute to axonal damage, which is a feature of the latter stages of the disease and is an important substrate of disability in the later, progressive phase of MS (Fig. 28.26).

Clinical features

The diagnosis of MS requires the demonstration of otherwise unexplained CNS lesions separated in time and space (Box 28.45); traditionally, this meant two or more clinical relapses affecting different parts of the nervous system, and the first-ever episode is often referred to as a ‘clinically isolated syndrome’ (CIS). However, recent changes to diagnostic criteria mean that MS may be diagnosed after an isolated episode because MRI can identify clinically silent lesions of different ages, and the presence of unpaired oligoclonal bands in the CSF can strongly suggest the development of future events (Box 28.45). As such MS can be proactively diagnosed and treated compared to a decade ago. The peak age of onset of MS is the fourth decade; onset in childhood or after the age of 70 years is less common but can occur.

Symptoms and signs of MS usually evolve over days or weeks, resolving over weeks or months. About 85%–90% of patients have an initial relapsing and remitting clinical course with variable intervening recovery, although the majority will eventually enter a secondary progressive phase. Most of the rest follow a slowly progressive clinical course (so-called...
Fig. 28.25 Multiple sclerosis. A Photomicrograph from demyelinating plaque, showing perivascular cuffing of blood vessel by lymphocytes. B Brain magnetic resonance imaging in multiple sclerosis. Multiple high-signal lesions (arrows) seen particularly in the paraventricular region on T2 image. C In T1 image with gadolinium enhancement, recent lesions (A arrows) show enhancement, suggesting active inflammation (enhancement persists for 4 weeks); older lesions (B arrows) show no enhancement but low signal, suggesting gliosis.

primary progressive MS). Aggressive variants of multiple sclerosis can occur, and this can include presentation with tumour-like lesions which may require biopsy for confirmation (see Fig. 28.26). The clinical course of multiple sclerosis is highly variable and difficult to predict. Frequent relapses with incomplete recovery indicate a poorer prognosis and the need for high efficacy therapy. Some milder cases have an interval of years or even decades between attacks.

*The diagnostic criteria require reasonable exclusion of other possible causes for central nervous system inflammation.

28.46 Clinical features of multiple sclerosis

- Optic neuritis
- Transverse myelitis
- Brainstem syndrome
- Cerebellar syndrome

Other symptoms and syndromes seen in MS

- Afferent pupillary defect and optic atrophy (previous optic neuritis)
- Lhermitte’s symptom (tingling in spine or limbs on neck flexion)
- Progressive paraparesis
- Partial Brown–Séquard syndrome (Fig. 28.18)
- Internuclear ophthalmoplegia with ataxia
- Tremor
- Cognitive dysfunction
- Trigeminal neuralgia under the age of 50

There are a number of typical clinical symptoms and syndromes suggestive of MS, occurring either at presentation or during the course of the illness (Box 28.46). The physical signs observed in MS are determined by the anatomical site of inflammation. Combined spinal cord and brainstem signs are common, although evidence of previous optic neuritis may be found in the form of an afferent pupillary deficit. Cognitive symptoms of MS are underappreciated and can be significant, particularly in the later stages of the disease.

The prognosis for patients with MS is difficult to predict with confidence, especially early in the disease. Those with untreated relapsing and remitting MS experience, on average, 1–2 relapses every 2 years, although this may decline with time. Prognosis is better for patients with optic neuritis and only sensory relapses. Overall, about one-third of patients are disabled to the point of needing help with walking after 10 years, and this proportion rises to about half after 15 years. It would appear likely (though this is as yet unproven) that disease-modifying drugs will have an effect on long-term disability.
Investigations

There is no single diagnostic test that is definitive for MS and the results of investigation need to be combined with the clinical picture in order to make a diagnosis; MRI is the most important investigation (Fig. 28.27). MS mimics should be excluded (see below). Following the first clinical event, investigations help confirm the disseminated nature of the disease. MRI is the most sensitive technique for imaging lesions in brain and spinal cord (Fig. 28.28) and for excluding causes that have provoked the neurological deficit. MS lesions often have an oval appearance and lesions which have developed in the past couple of months usually take up contrast around the lesion rim. Typical MRI lesion locations include the periventricular region, juxtacortical, infratentorial regions and spinal cord. Spinal cord lesions in MS are typically short and are asymmetric (Fig. 28.29). Longer spinal cord lesions, over 3 vertebral bodies in length, should raise the possibility of neuromyelitis optica, an antibody-mediated neuroinflammatory disease. In older age groups, MRI appearances in MS may be confused with those of small-vessel disease and non-specific white matter lesions can be seen in common conditions such as migraine. Therefore careful and experienced evaluation of brain and spinal cord imaging is important for accurate diagnosis.

In MS, the CSF typically has a normal white cell count and protein, although may show a small lymphocytic pleocytosis in active disease. CSF can be used to identify intrathecal synthesis of immunoglobulins in MS. Oligoclonal bands are found in the CSF but not the blood in about 90% of patients. The presence of these bands can help facilitate a more rapid diagnosis of MS in individuals who have had a single clinical event, since they suggest a more chronic neuroinflammatory process. Oligoclonal bands are not specific for MS and denote only intrathecal inflammation, provided they are unique for the CSF. These can appear in other disorders, which should be excluded by examination and investigation. It is important to exclude other potentially treatable conditions, such as infection, vitamin $B_{12}$ deficiency and spinal cord compression.

Management

The management of MS involves (i) disease modifying therapies and (ii) symptomatic approaches.

Disease-modifying treatment (DMT)

The past two decades have seen enormous progress in the treatment of multiple sclerosis, in particular the treatment of early MS. There is a broad spectrum of immunotherapies for the treatment of MS, with >10 drugs approved in Europe and the United States. These drugs are most efficacious in the relapsing–remitting phase of disease, and early diagnosis and treatment is increasingly viewed as important in improving long-term outcomes. All DMTs reduce relapse frequency and higher efficacy drugs, for example B-cell depleting monoclonal antibodies, reduce the development of disability. Recently, immunotherapies have also been approved to prevent disability in progressive forms of MS, although only where active inflammation can be demonstrated. In general, drugs with higher efficacy are associated with more serious side-effects and clinical trials are under way to determine the optimum level of immune treatment early in the course of MS (Box 28.47). Careful selection and counselling of patients are necessary and these drugs should be supervised by teams experienced in their use, as recommended in national guidelines. Some DMTs can be used during pregnancy, but MS specialist advice should be sought.

Smoking, poor diet and obesity are risk factors for disease progression in MS, and should be addressed as early as possible.

The acute relapse

In a disabling relapse of MS, pulses of high-dose glucocorticoid, given either intravenously or orally over 3–5 days, will shorten the duration of the acute episode, but will not affect long-term recovery. If a patient develops a new neurological deficit whilst on a DMT, consideration should also be given to possible neurological side-effects of the drug (e.g. visual loss due to fingolimod-associated macular oedema, cognitive symptoms caused by natalizumab-associated PML).

Fig. 28.27 Investigations in a patient suspected of having multiple sclerosis.
Treatment of symptoms, complications and disability

Treatments for the complications of MS are summarised in Box 28.48. It is important to provide patients with a careful explanation of the nature of the disease and its outcome. Specialist nurses working in a multidisciplinary team of health-care professionals are of great value in managing the chronic phase of the disease. Periods of physiotherapy and occupational therapy may improve functional capacity in those who become disabled, and guidance can be provided on the use of aids at home. Bladder care is particularly important. Urgency and frequency can be treated pharmacologically (see Box 28.22) but this may lead to a degree of retention with an attendant risk of infection. Urinary retention can be managed initially by intermittent urinary catheterisation but an in-dwelling catheter may become necessary. It is important to address sexual dysfunction, which can occur and is a frequent source of distress. Pregnancy does not increase the risk of progression of MS but relapses may occur post-partum (Box 28.49).

Acute disseminated encephalomyelitis

This is an acute, often severe monophasic demyelinating condition in which areas of periventricular demyelination are widely disseminated throughout the brain and spinal cord. The illness may arise spontaneously but often occurs a week or so after a viral infection, especially measles or chickenpox, or following vaccination, suggesting that it is immunologically mediated.

Clinical features

Headache, vomiting, pyrexia, delirium and meningism may be presenting features, often with focal or multifocal brain and spinal cord signs. Seizures or coma may occur. A minority of patients who recover have further episodes.

Investigations

MRI shows multiple high-signal areas in a pattern similar to that of MS, although often with large confluent areas of abnormality. CSF may be normal or show an increase in protein and lymphocytes (occasionally > 100×10⁶ cells/L). Oligoclonal bands may be found in the acute episode but, in contrast to MS, do not persist beyond clinical recovery. The clinical picture may be very similar to a first relapse of MS.

Management

The prognosis for acute disseminated encephalomyelitis is generally good, although occasionally it may be fatal. Treatment with high-dose intravenous methylprednisolone, using the same regimen as for a relapse of MS, is recommended.
Transverse myelitis

Transverse myelitis is an acute, usually monophasic, demyelinating disorder affecting the spinal cord. It is sometimes thought to be post-infectious in origin. It occurs at any age and presents with a subacute paraparesis with a sensory level, accompanied by severe pain in the neck or back at the onset. MRI should distinguish this from an external lesion affecting the spinal cord. CSF examination shows cellular pleocytosis. Oligoclonal bands are usually absent. Treatment is with high-dose intravenous methylprednisolone. The outcome is variable: one-third have static deficit, one-third go on to develop MS and one-third recover with no subsequent relapse. Some clinical features may suggest a higher risk of MS after transverse myelitis.

Neuromyelitis optica

Neuromyelitis optica spectrum disorder (NMOSD, previously Devic disease) typically presents with severe optic neuritis or longitudinally extensive transverse myelitis. NMO can also cause severe vomiting or hiccups due to brainstem dysfunction. With cord presentations, spinal MRI scans show lesions that are typically longer than three spinal segments. The majority of cases are associated with an antibody against an astrocytic water channel, aquaporin 4. It is likely that this is a pathogenic antibody. The presence of aquaporin 4 antibodies is a strong predictor of future relapse. More recently it is recognised that some cases of NMOSD can be associated with myelin oligodendrocyte glycoprotein-associated MOG antibodies, although these patients might be less prone to relapse. A proportion of NMOSD are not associated with known antibodies. Brain lesions can be seen on MRI, but are less prominent than in MS and can develop in aquaporin 4-rich areas around the base of the fourth ventricle. Clinical deficits tend to recover less well than in MS, and the disease may be more aggressive with more frequent relapses. Treatment with glucocorticoids, oral immunosuppression and rituximab is often used. Recent clinical trials have suggested efficacy of B-cell depletion, IL-6 blockade and complement inhibition (Fig. 28.29).

Autoimmune encephalitis

Autoimmune encephalitis (AE) is an immune-mediated brain disease which can occur at any age and presents with cognitive symptoms, behavioural change and seizures. AE can occasionally develop following a preceding infection and should be considered if there is an inflammatory deterioration following recovery from an initial brain infection. AE can present with distinct clinical syndromes and these are associated with specific autoantibodies directed against neuronal cell surface antigens. Limbic encephalitis presents with memory disturbance (and can mimic neurodegenerative dementia in older persons), emotional and behavioural disturbance and seizures, which can cause brief dystonic movements of the face and arm (facio-brachial dystonic seizures). MRI may show enhancement and inflammation in hippocampus and associated limbic structures, and there are often mild inflammatory changes in the CSF. There is a strong association with Lgi1 and CASPR2 antibodies.

AE can also be associated with NMDAR antibodies, and this syndrome typically presents with neuropsychiatric symptoms, movement disorders, autonomic dysfunction and seizures and often causes
serious illness requiring intensive care admission. A subset of NMDAR encephalitis is associated with ovarian teratoma. Corticosteroids, immune globulin and plasma exchange are often used acutely. AE can relapse or follow a chronic course and long-term immunosuppression with oral immunosuppressants, cyclophosphamide or rituximab may be needed.

Paraneoplastic neurological disorders

Neurological disease may occur with systemic malignant tumours in the absence of cerebral metastases. It is now recognised that, in the majority of these cases, antigen production in the body of the tumour leads to development of antibodies to parts of the CNS. Paraneoplastic conditions are increasingly recognised and the number of antibodies identified is also growing (Box 28.50). These syndromes are particularly associated with small-cell carcinoma of lung, ovarian tumours and lymphomas. Autoantibodies are found in the serum and/or CSF, and biopsy will show a lymphocytic infiltrate of the neural tissue affected.

Clinical features

Clinical presentations are summarised in Box 28.50. In most instances, the neurological condition progresses quite rapidly over a few months, preceding the malignant disease in around half of cases. The range of clinical patterns is so wide that paraneoplastic disease should be considered in the diagnosis of any unusual progressive neurological syndrome. The paraneoplastic disorders of the peripheral nervous system particularly affect the synaptic cleft (p. 1122).

Investigations and management

The presence of characteristic autoantibodies in the context of a suspicious clinical picture may be diagnostic. The causative tumour may be very small and therefore CT of the chest or abdomen or PET scanning may be necessary to find it. These investigations should be pursued only when paraneoplastic disease has been proven, rather than when it is suspected. The CSF often shows an increased protein and lymphocyte count with oligoclonal bands.

Treatment is directed at the primary tumour. Occasionally, successful therapy of the tumour is associated with improvement of the paraneoplastic syndrome. Some improvement may occur following administration of intravenous immunoglobulin.

Neurodegenerative diseases

While MS is the most common cause of disability in young people in the UK, vascular and neurodegenerative diseases are increasingly important in later life. The neurodegenerative diseases are united in having a pathological process that leads to specific neuronal death, causing relentlessly progressive symptoms, with incidence rising with age. The causes are not yet known, although genetic influences are important. Alzheimer’s disease and Parkinson’s disease are the most common.

Movement disorders

Movement disorders present with a wide range of symptoms. They may be genetic or acquired, and the most important is Parkinson’s disease. Most movement disorders are categorised clinically, with few confirmatory investigations available other than for those with a known gene abnormality.

Idiopathic Parkinson’s disease

Parkinsonism is a clinical syndrome characterised primarily by bradykinesia, with associated increased tone (rigidity), tremor and loss of postural reflexes. There are many causes (Box 28.51) but the most common is Parkinson’s disease (PD). PD has an annual incidence of about 18/100,000 in the UK and a prevalence of about 180/100,000. Age has a critical influence on incidence and prevalence, the latter rising to 300–600/100,000 after 80 years of age. The global prevalence of PD (over 6 million in 2016) more than doubled between 1990 and 2016 with increases across all socio-demographic regions of the world, related mainly to increasing age and longer disease duration. Average age of onset is about 60 years and fewer than 5% of patients present under the age of 40. Genetic factors are increasingly recognised and several single genes causing parkinsonism have been identified. Monogenic Parkinson’s disease can be caused by mutations in SNCA (which encode alpha-synuclein), as well as Parkin, PINK1, DJ-1 and many more, although overall monogenic disease accounts for a very small proportion of cases overall. Mutations in the LRRK2 gene are the most frequent genetic cause of late-onset PD. Having a first-degree relative with PD confers a 2–3 times
increased risk of developing the disorder. It is progressive and incurable, with a variable prognosis. While motor symptoms are the most common presenting features, non-motor symptoms (particularly cognitive impairment, depression and anxiety) become increasingly prominent as the disease progresses, and significantly reduce quality of life.

Pathophysiology

Although mutations in several genes have been identified in a few cases, in most patients the cause remains unknown. The discovery that methylphenyl-tetrahydrodpyridine (MPTP) caused severe parkinsonism in young drug users suggested that PD might be due to an environmental toxin but none has been convincingly identified. The pathological hallmarks of PD are depletion of the pigmented dopaminergic neurons in the substantia nigra and the presence of α-synuclein and other protein inclusions in nigral cells (Lewy bodies; Fig. 28.30). It is thought that environmental or genetic factors alter the α-synuclein protein, rendering it toxic and leading to Lewy body formation within the nigral cells. Lewy bodies are also found in the basal ganglia, brainstem and cortex, and increase with disease progression. PD is recognised as a synucleinopathy alongside multiple system atrophy and dementia with Lewy bodies. The loss of dopaminergic neurotransmission is responsible for many of the clinical features.

Clinical features

Non-motor symptoms, including reduction in sense of smell (hyposmia), anxiety/depression, constipation and REM sleep behavioural disturbance (RBD), may precede the development of typical motor features by many years but patients rarely present at this stage. The motor symptoms are almost always initially asymmetrical. The hallmark is bradykinesia, leading to classic symptoms such as increasingly small handwriting (‘micrographia’), difficulty tying shoelaces or buttoning clothes, and difficulty rolling over in bed. Tremor is an early feature but may not be present in at least 20% of people with PD. It is typically a unilateral rest tremor affecting limbs, jaw and chin but not the head. In some patients tremor remains the dominant symptom for many years. Rigidity causes stiffness and a flexed posture. Although postural righting reflexes are impaired early on in the disease, falls tend not to occur until later. As the disease advances, speech becomes softer and indistinct. There are a number of abnormalities on neurological examination (Box 28.52).

Although features are initially unilateral, gradual bilateral involvement evolves with time. Cognition is spared in early disease; if impaired, it should trigger consideration of alternative diagnoses, such as dementia with Lewy bodies.

Non-motor symptoms

While non-motor symptoms may precede the onset of more typical symptoms by many years, for most patients these features become increasingly common and disabling as PD progresses. Cognitive impairment, including dementia, is the symptom most likely to impair quality of life for patients and their carers. Estimates of dementia frequency range from 30% to 80%, depending on definitions and length of follow-up. Other distressing non-motor symptoms include neuropsychiatric features (anxiety, depression, apathy, hallucinosis-psychosis), sleep disturbance and hypersomnia, fatigue, pain, sphincter disturbance and constipation, sexual problems (erectile failure, loss of libido or hypersexuality), drooling and weight loss.

Investigations

The diagnosis is clinical. Structural imaging (CT or MRI) is usually normal for age and thus rarely helpful, although it may support a suspected vascular cause of parkinsonism. Functional dopaminergic imaging (SPECT or PET) is abnormal, even in the early stages (Fig. 28.31), but does not differentiate between the different forms of degenerative parkinsonism (see Box 28.51) and so is not specific for PD. In younger patients, specific investigations may be appropriate (e.g. exclusion of Huntington’s or Wilson’s diseases). Some patients with family histories may wish to consider genetic testing, although the role of genetic counselling is uncertain at present.

Management

Drug therapy

Drug treatment for PD remains symptomatic rather than curative, and there is no evidence that any of the currently available drugs are neuroprotective. Levodopa (LD) remains the most effective treatment.
available but other agents include dopamine agonists, anticholinergics, inhibitors of monoamine oxidase (MAO)-B and catechol-O-methyltransferase (COMT), and amantadine. Debate continues about when and what treatment should be started. In general, most specialists recommend initiating treatment when symptoms are impacting on everyday life, although some favour treatment as soon as the diagnosis is made. Whether it is best to start with LD, a dopamine agonist or MAO-B remains unclear but most accept that the most effective, best-tolerated and cheapest drug is LD. Many motor symptoms, such as tremor, freezing, falling, head-drop and abnormal flexion, are quite resistant to treatment. Some non-motor symptoms, such as anxiety or depression, may respond to drug or non-drug treatments. In the UK, rivastigmine is licensed for use in PD-associated dementia, although its effect is modest. Many other non-motor symptoms are resistant to treatment. Drugs for PD should not be stopped abruptly, as this can precipitate malignant hyperthermia.

Levodopa Levodopa is the precursor to dopamine. When administered orally, more than 90% is decarboxylated to dopamine peripherally in the gastrointestinal tract and blood vessels, and only a small proportion reaches the brain. This peripheral conversion is responsible for the high frequency of adverse effects. To avoid this, LD is combined with a dopa decarboxylase inhibitor (DDI); the inhibitor does not cross the blood–brain barrier, thus avoiding unwanted decarboxylation-blocking in the brain. Two DDIs, carbidopa and benserazide, are available as combination preparations with LD (Sinemet and Madopar, respectively).

LD is most effective for relieving akinesia and rigidity; tremor response is often less satisfactory and it has no effect on many motor (posture, freezing) and non-motor symptoms. Failure of akinesia/rigidity to respond to LD (1000 mg/day) should prompt reconsideration of the diagnosis. Although controlled-release versions of LD exist, these are usually best reserved for use overnight, as their variable bioavailability makes them difficult to use throughout the day. Madopar is also available as a dispersible tablet for more rapid-onset effect. Adverse effects include postural hypotension, nausea and vomiting, which may be offset by dopemidone, though this is only prescribed for brief periods, if essential, given the risk of prolonged QTc interval and arrhythmia. LD may exacerbate or trigger hallucinations, and abnormal LD-seeking behaviour (dopamine dysregulation syndrome), in which the patient takes excessive doses of LD, may occur uncommonly.

As PD progresses, the response to LD becomes less predictable in many patients, leading to motor fluctuations. This end-of-dose deterioration is due to progressive loss of dopamine storage capacity by dwindling numbers of striatongiral neurons. LD-induced involuntary movements (dyskinesia) may occur as a peak-dose phenomenon or as a biphasic phenomenon (occurring during both the build-up and wearing-off phases). More complex fluctuations present as sudden, unpredictable changes in response, in which periods of parkinsonism (‘off’ phases) alternate with improved mobility but with dyskinesias (‘on’ phases). Motor complication management is difficult; wearing-off effects may respond to increased dose or frequency of LD or the addition of a COMT inhibitor (see below). More complex fluctuations may be improved by the addition of dopamine agonists (including continuous infusion of apomorphine), use of intraintestinal LD via a percutaneous endoscopic jejunostomy, or deep brain stimulator implantation.

Dopamine receptor agonists Originally introduced in the hope of delaying the initiation of LD and thus delaying motor complications, several dopamine agonists are available, and may be delivered orally, transdermally, sublingually, intranasally or subcutaneously (Box 28.53). The ergot-derivative agonists are no longer recommended because of rare but serious fibrotic side-effects. With the exception of apomorphine, all the agonists are considerably less effective than LD in relieving parkinsonism, have more adverse effects (nausea, vomiting, disorientation and hallucinations, impulse control disorders) and are more expensive. Their role in the management of PD (monotherapy or adjunctive) remains uncertain, and evidence suggests that their usefulness as initial mono-therapy is short-lasting.

MAO-B inhibitors Monoamine oxidase type B facilitates breakdown of excess dopamine in the synapse. Two inhibitors are used in PD: sele-giline and rasagiline. The effects of both are modest, although usually well tolerated. Neither is neuroprotective, despite initial hopes.

COMT inhibitors Catechol-O-methyl-transferase (along with dopa decarboxylase) is involved in peripheral breakdown of LD. Three inhibitors are available: entacapone, opicapone and tolcapone (which also inhibits central COMT). Entacapone has a modest effect and is most useful for early wearing-off. It is available either as a single tablet taken with each LD/DDI dose, or as a combination tablet with LD and DDI. The more potent tolcapone is less used because of rare but serious hepatotoxicity. Opicapone, the newest of the three, is available as a once-daily drug.

Amantadine This has a mild, usually short-lived effect on bradykinesia and is rarely used unless patients are unable to tolerate other drugs. It is more commonly employed as a treatment for LD-induced dyskinesias, although again benefit is modest and short-lived. Adverse effects include headache, dizziness, peripheral oedema, delirium and other anticholinergic effects.

Anticholinergic drugs These were the main treatment for PD prior to the introduction of LD. Their role now is limited by lack of efficacy (apart from an effect on tremor sometimes) and adverse effects, including dry mouth, blurred vision, constipation, urinary retention, delirium and hallucinosis, as well as long-term concerns regarding cognitive impairment. Several anticholinergics are available, including trihexyphenidyl (benzhexol) and orphenadrine.
Corticobasal degeneration

Corticobasal degeneration (CBD) is less common than MSA or PSP, and the clinical manifestations are variable, including parkinsonism, dystonia, myoclonus and ‘alien limb’ phenomenon, whereby a limb (usually upper) moves about or interferes with the other limb without apparent conscious control. Cortical symptoms, including dementia and especially apraxia, are common and may be the only features in some cases. A number of other diseases may present with a cortico basal syndrome, including other dementias. CBD is a tauopathy with widespread deposition throughout the brain and has similar survival rates to MSA and PSP.

Wilson’s disease

This is an autosomal recessive disorder resulting from mutation in the ATP7B gene, causing a defect of copper metabolism (p. 907). It is a treatable cause of various movement disorders, including tremor, dystonia, parkinsonism and ataxia; psychiatric symptoms may also occur. Wilson’s disease should always be excluded in patients under the age of 50 presenting with any movement disorder.

Huntington’s disease

Huntington’s disease (HD) is an autosomal dominant disorder, presenting in adults usually but occasionally in children. It is due to expansion of a trinucleotide CAG repeat in the Huntingtin gene on chromosome 4 (see Box 3.2). The disease frequently demonstrates the phenomenon of anticipation, in which there is a younger age at onset as the disease is passed through generations, due to progressive expansion of the repeat. The prevalence is about 4–8/100,000.

Clinical features

HD typically presents with a progressive behavioural disturbance, abnormal movements (usually chorea) and cognitive impairment leading to dementia. Onset under 18 years is rare but patients may then present with parkinsonism rather than chorea (the “Westphal variant”). There is always a family history, although this may not always be apparent and can sometimes be concealed.

### Investigations and management

The diagnosis is confirmed by genetic testing; pre-symptomatic testing for other family members is available but must be preceded by appropriate counselling. Brain imaging may show caudate atrophy but is not a reliable test. There are a number of HD mimics.

Management is symptomatic, though antisense oligonucleotide therapy to reduce the Huntingtin gene (HTT) product is currently being trialled. The chorea may respond to neuroleptics such as risperidone or sulpiride, or tetrabenazine. Depression and anxiety are common and may be helped by medication.

### Ataxias

The ataxias are a heterogeneous group of inherited and acquired disorders, presenting either with pure ataxia or in association with other neurological and non-neurological features. The differential is wide (Boxes 28.54 and 28.55), and diagnosis is guided by age of onset, evolution and clinical features. A significant proportion of cases remain idiopathic despite investigation.

The hereditary ataxias are a group of inherited disorders in which degenerative changes occur to varying extents in the cerebellum, brainstem, pyramidal tracts, spinocerebellar tracts and optic and peripheral nerves, and influence the clinical manifestations. Onset ranges from infancy to adulthood, with recessive, sex-linked or dominant inheritance (see Box 28.55). While the genetic abnormality has been identified for some, allowing diagnostic testing, this is not currently the case for many of the hereditary ataxias.

### Drug-induced tremor (usually postural)*

- β-agonists (e.g. salbutamol)
- Theophylline
- Sodium valproate
- Thyroxine
- Lithium
- Tricyclic antidepressants
- Recreational drugs (e.g. amphetamines)
- Alcohol
- Caffeine

*Drugs causing parkinsonism and associated tremor are listed in Box 28.51.

### Tremor disorders

Tremor is a feature of many disorders but the most important clinical syndromes are PD, essential tremor, drug-induced tremors (Box 28.56) and functional (psychogenic) tremors.

### Essential tremor

This has a prevalence of about 300/100,000 and may display a dominant pattern of inheritance, although no genes have thus far been identified. It may present at any age with a bilateral arm tremor (8–10 Hz), rarely at rest but typical with movement. The head and voice may be involved. The tremor improves in about 50% of patients with small amounts of alcohol. There are no specific tests and essential tremor should be distinguished from other tremor syndromes, including dystonic tremor. Beta-blockers and primidone are sometimes helpful, and DBS of the thalamus is an effective treatment for severe cases.
Dystonia

Dystonia is characterised by a focal increase in tone affecting muscles in the limbs or trunk. It may be a feature of a number of neurological conditions (PD, Wilson’s disease), or occur secondary to brain damage (trauma, stroke) or drugs (tardive syndromes). Dystonia also occurs as a primary disorder. With childhood onset the cause is usually genetic and dystonia is generalised, but adult onset is usually focal; examples include a twisted neck (torticollis), repetitive blinking (blepharospasm) or tremor. Task-specific symptoms (e.g. writer’s cramp, musician’s dystonia) are often dystonic. Treatment is difficult but botulinum toxin injections or DBS may be useful.

Hemifacial spasm

This usually presents after middle age with intermittent twitching around one eye, spreading ipsilaterally to other facial muscles. The spasms are exacerbated by talking, eating and stress. Hemifacial spasm is usually idiopathic, similar to trigeminal neuralgia; it has been suggested that it may be due to an aberrant arterial loop irritating the 7th nerve just outside the pons. It may, however, be symptomatic and secondary to structural lesions. Drug treatment is not effective but injections of botulinum toxin into affected muscles help, although these usually have to be repeated every 3 months or so. In refractory cases, microvascular decompression may be considered.

Motor neuron disease

Motor neuron disease (MND) is a neurodegenerative condition caused by loss of upper and lower motor neurons in the spinal cord, cranial nerve nuclei and motor cortex. Annual incidence is about 2/100,000, with a prevalence of about 7/100,000. Most cases are sporadic but 10% of cases are familial and mutations in C9orf72 (repeat expansion), SCAD1, VCP, FUS and TARDBP/TDP43 are found in many of these monogenic cases and may influence clinical phenotype and course, in particular overlap with frontotemporal dementia. The most common form of MND (Fig. 28.32) is amyotrophic lateral sclerosis (ALS), and many use the terms MND and ALS interchangeably. ALS is characterised by a combination of upper and lower motor neuron signs; there are rare, pure lower (progressive muscular atrophy) or upper (progressive lateral sclerosis) motor neuron variants of MND. The average age of onset is 65, with 10% presenting before 45 years.

Clinical features

Diagnosis can be difficult and is often delayed. MND typically presents focally, either with limb onset (e.g. foot drop or loss of manual dexterity) or with bulbar symptoms (dysarthria, swallowing difficulty); respiratory onset is rare but type II respiratory failure is a common cause of death. Sensory, autonomic and visual symptoms do not occur, although cramp is common (Box 28.57). Examination reveals a combination of lower and upper motor neuron signs (e.g. brisk reflexes in wasted, fasciculating muscles) without sensory involvement (see Fig. 28.32). Cognitive impairment is under-recognised in MND: up to 50% will have a mainly executive impairment on formal testing, and around 10% develop a frontotemporal dementia (FTD). About 10% of patients presenting with FTD will develop ALS within a few years of dementia onset. Even with treatment, MND is relentlessly progressive, but median survival is improved with specialist follow-up offering non-invasive ventilation, feeding measures and access to pharmacological treatment.

Investigations

Clinical features are often typical but alternative diagnoses should be excluded. Exclusion of treatable causes, such as immune-mediated

| 28.57 Clinical features of motor neuron disease |

Onset
- Usually after the age of 50 years
- Very uncommon before the age of 30 years
- Affects males more commonly than females

Symptoms
- Limb muscle weakness, cramps, occasionally fasciculation
- Disturbance of speech/swallowing (dysarthria/dysphagia)
- Cognitive and behavioural features common (similar to frontotemporal dementia)

Signs
- Wasting and fasciculation of muscles
- Weakness of muscles of limbs, tongue, face and palate
- Pyramidal tract involvement, causing spasticity, exaggerated tendon reflexes, extensor plantar responses
- External ocular muscles and sphincters usually remain intact
- No objective sensory deficit
- Evidence of cognitive impairment with frontotemporal dominance

Course
- Symptoms often begin focally in one part and spread gradually but relentlessly to become widespread

Fig. 28.32 Patterns of involvement in motor neuron disease. (LMN = lower motor neuron; UMN = upper motor neuron)
multifocal motor neuropathy with conduction block (p. 1192) and cervical myeloradiculopathy, is essential. Blood tests are usually normal, other than a mildly raised creatine kinase. Sensory and motor nerve conduction studies are normal but there may be reduction in amplitude of motor action potentials due to axonal loss. EMG will usually confirm the typical features of widespread denervation and re-innervation. Spinal fluid analysis is not usually necessary. Genetic testing is increasing in importance, with mutations found in SOD1, FUS, TARDBP and C9or72 that may help predict risk of disease in those with a family history of MND.

Management

Patients should be managed within a multidisciplinary service, including physiotherapists, speech and occupational therapists, dietitians, ventilatory and feeding support, and palliative care teams, with neurological and respiratory input. Riluzole, a glutamate release antagonist, is licensed for ALS but has only a modest effect, prolonging median survival by about 2–3 months.

Non-invasive ventilation significantly prolongs survival and improves or maintains quality of life in people with ALS. Survival and some measures of quality of life are significantly improved in the subgroup of people with better baseline bulbar function but not in those with severe bulbar impairment. Feeding by percutaneous gastrostomy may improve quality of life and prolong survival, even when done at a late stage. Rapid access to palliative care teams is essential for patients as they enter the terminal stages of MND.

Spinal muscular atrophy

This is a group of genetically determined recessive disorders affecting spinal and cranial lower motor neurons, characterised by proximal and distal wasting, fasciculation and weakness of muscles. Most SMA cases are caused by a defective SMN1 gene. Involvement is usually symmetrical but occasional localised forms occur. With the exception of the infantile form, progression is slow and the prognosis better than for MND. Sophisticated nucleic acid-based therapies for the treatment of SMA have shown significant promise. Intrathecally delivered antisense oligonucleotide therapies can partially correct this SMN1 genetic defect and show clinical efficacy in severe forms of the disease.

Infections of the nervous system

The clinical features of nervous system infections depend on the location of the infection (the meninges or the parenchyma of the brain and spinal cord), the causative organism (virus, bacterium, fungus or parasite), and whether the infection is acute or chronic. The major infections of the nervous system are listed in Box 28.58. The frequency of these varies geographically and in relation to socio-economic level. While certain infections, e.g. tuberculosis and cysticercosis, may not be prevalent in the United Kingdom, they are common in other regions and, therefore, occur in returning travellers or immigrants. Protozoal infections are described in Chapter 13.

Meningitis

The characteristic clinical features of acute infection of the meninges are pyrexia, headache and meningism. Meningism consists of headache, photophobia and stiffness of the neck, sometimes accompanied by other signs of meningeal irritation, including Kernig’s sign (extension at the knee with the hip joint flexed causes spasm in the hamstring muscles) and Brudzinski’s sign (passive flexion of the neck causes flexion of the hips and knees). However, as discussed in Chapter 1, meningitis frequently presents without meningism, and although Kernig's and Brudzinski's signs are specific, their sensitivity can be as low as 5%. Therefore, meningitis should be considered in anyone who presents with fever and headache. Altered level of consciousness may occur and is more common in older people. Abnormalities in the CSF (see Box 28.6) are important in distinguishing the cause of meningitis. Causes of meningitis are listed in Box 28.59.

Viral meningitis

Viruses are the most common cause of meningitis, usually resulting in a benign and self-limiting illness requiring no specific therapy. It is much less serious than bacterial meningitis unless there is associated encephalitis. A number of viruses can cause meningitis (see Box 28.59), the most common being enteroviruses. Where specific immunisation is not employed, the mumps virus is a common cause.

Clinical features

Viral meningitis occurs mainly in children or young adults, with acute onset of headache and irritability and the rapid development of meningism. The headache is usually the most severe feature. There may be a high pyrexia but focal neurological signs are rare.

Investigations

The diagnosis is made by lumbar puncture, with the specific viral cause identified by a nucleic acid amplification test (NAAT). CSF usually contains an excess of lymphocytes. While glucose and protein levels are commonly normal, the latter may be raised. It is important to verify that the patient has not received antibiotics (for whatever cause) prior to the lumbar puncture, as CSF lymphocytosis can also be found in partially treated bacterial meningitis (see Box 28.6).

Management

There is no specific treatment and the condition is usually benign and self-limiting. The patient should be treated symptomatically in a quiet environment. Recovery usually occurs within days, although a lymphocytic pleocytosis may persist in the CSF. Meningitis may also occur as a complication of a systemic viral infection such as mumps, measles, infectious mononucleosis, varicella zoster and hepatitis. Whatever the virus, complete recovery without specific therapy is the rule.
28.59 Causes of meningitis

**Infective**

**Bacteria**
- Streptococcus pneumoniae
- Neisseria meningitidis (serogroups A, B, C, Y, W135)
- Mycobacterium tuberculosis
- Haemophilus influenzae
- Listeria monocytogenes
- Other streptococci including Strep. suis
- Staphylococcus aureus (skull fracture)

**Viruses**
- Enteroviruses (echo, Coxackie, polio)
- Herpes simplex virus type 2 (Mollaret’s meningitis)
- Varicella zoster virus
- Herpes simplex type 1
- Epstein–Barr virus
- Cytomegalovirus
- Measles

**Fungi**
- Cryptococcus neoformans
- Candida
- Histoplasma
- Blastomyces
- Coccidioides
- Sporothrix

**Non-infective (‘sterile’)**

**Malignant disease**
- Breast cancer
- Bronchogenic cancer
- Leukaemia
- Lymphoma

**Inflammatory disease (may be recurrent)**
- Sarcoidosis
- Systemic lupus erythematosus
- Behçet’s disease

28.61 Complications of meningococcal sepsis

- Meningitis
- Rash (morbilliform, petechial or purpuric)
- Shock
- Intravascular coagulation
- Renal failure
- Peripheral gangrene
- Arthritis (septic or reactive)
- Pericarditis (septic or reactive)

**Bacterial meningitis**

Many bacteria can cause meningitis but geographical patterns vary, as does age-related sensitivity (Box 28.60). In the ‘meningitis belt’ of sub-Saharan Africa, drought and dust storms are often associated with meningococcal outbreaks (Hammattan meningitis). Bacterial meningitis is usually part of a bacteraemic illness, although direct spread from an adjacent focus of infection in the ear, skull fracture or sinus can be causative. Antibiotics have rendered this less common but mortality and morbidity remain significant. An important factor in determining prognosis is early diagnosis and the prompt initiation of appropriate therapy. Most bacterial causes of meningitis are normal commensals of the upper respiratory tract. New and potentially pathogenic strains are acquired by droplet spread but close contact is necessary. Epidemics of meningococcal meningitis occur, particularly in cramped living conditions or where the climate is hot and dry. The organism invades through the nasopharynx, producing sepsis and leading to meningitis.

**Pathophysiology**

*Streptococcus pneumoniae* (pneumococcus) and *Neisseria meningitidis* (meningococcus) are the commonest causes of bacterial meningitis globally, including in the United Kingdom. *Streptococcus suis* is a rare zoonotic cause of meningitis associated with porcine contact. It is an important cause of meningitis in some parts of Asia, including Vietnam and Thailand. Some degree of hearing loss occurs in more than half of survivors. Infection stimulates an immune response, causing the pia-arachnoid membrane to become congested and infiltrated with inflammatory cells. The pro-inflammatory immune mediators released are particularly prominent in *Streptococcus pneumoniae* infection and may account for the poor prognosis associated with pneumococcal meningitis. Pus then forms in layers, which may later organise to form adhesions. These may obstruct the free flow of CSF, leading to hydrocephalus, or they may damage the cranial nerves at the base of the brain. Hearing loss is a frequent complication. The CSF pressure rises rapidly, the protein content increases, and there is a cellular reaction that varies in type and severity according to the nature of the inflammation and the causative organism. An obliterative endarteritis of the leptomeningeal arteries passing through the meningeal eudate may produce secondary cerebral infarction. Pneumococcal meningitis is often associated with a very purulent CSF and a high mortality, especially in older adults.

**Clinical features**

The most common presenting features are fever and headache, which may also be associated with drowsiness and meningism. More than 90% of patients have any two of: headache, pyrexia, meningism and altered consciousness. Rash may occur in meningococcal meningitis. In severe bacterial meningitis the patient may be comatose, later developing focal neurological signs. Seizures may occur in around a quarter of patients. When accompanied by sepsis, presenting signs may evolve rapidly, with abrupt onset of obtundation due to cerebral oedema. Complications of meningococcal sepsis are listed in Box 28.61. Chronic meningococcaemia is a rare condition in which the patient can be unwell for weeks or even months with recurrent fever, sweating, joint pains and transient rash. In pneumococcal and Haemophilus infections there may be an accompanying otitis media. Pneumococcal meningitis may be associated with pneumonia and occurs especially in older patients and alcoholics, as well as those with hypoplasia. Listeria monocytogenes causes meningitis and rhombencephalitis (brainstem encephalitis) in the immunosuppressed, people at the extremes of age (neonates and older adults), with diabetes, alcoholics and pregnant women.

**Investigations**

Lumbar puncture is mandatory unless there are contraindications. If the patient is drowsy and has focal neurological signs or seizures, is immunosuppressed, has undergone recent neurosurgery or has suffered a head injury, it is wise to obtain a CT to exclude a mass lesion (such as a cerebral abscess) before lumbar puncture because of the risk of coning. This should not, however, delay treatment of presumed meningitis. If lumbar puncture is deferred or omitted, it is essential to take blood cultures and to start empirical treatment (Fig. 28.33). Lumbar puncture will help differentiate the causative organism but the characteristic findings in bacterial meningitis listed in Box 28.6 are far from universal. If the CSF is abnormal, the safest
course is to treat for bacterial meningitis. A bloody tap may complicate CSF findings. The safest approach is to treat for bacterial meningitis if the white cell count is above normal and disregard the red cell count. Gram film and culture may allow identification of the organism. Blood cultures may be positive. PCR techniques can be used on both blood and CSF to identify bacterial DNA for several days after antibiotic treatment has started.

**Management**

There is an untreated mortality rate of around 80%, so action must be swift. Antibiotics should ideally be given after CSF and blood cultures have been obtained, but if there is any delay obtaining these samples, antibiotic therapy should be started immediately. Recommended empirical therapies are outlined in Box 28.62, and the preferred antibiotic when the organism is known after CSF examination is stipulated in Box 28.63. Some regions of the world have a high prevalence of penicillin resistance and local guidelines or microbiologist advice should be sought. There is remarkably little evidence to guide duration of antibiotic treatment. As a guide, pneumococcal meningitis should be treated for 10–14 days, meningococcal meningitis slightly less (around 7 days) and *Listeria* meningitis for 21 days. Adjunctive glucocorticoid therapy is useful in reducing hearing loss and neurological sequelae in both children and adults in high-income countries, but evidence does not support the use of dexamethasone in lower-income countries or where there are high rates of untreated HIV.

In meningococcal disease, mortality is doubled if the patient presents with features of sepsis rather than meningitis. Individuals likely to require intensive care facilities and expertise include those with cardiac, respiratory or renal involvement, and those with CNS depression prejudicing the airway. Early endotracheal intubation and mechanical ventilation protect the airway and may prevent the development of the acute respiratory distress syndrome (ARDS). Adverse prognostic features include hypotensive shock, a rapidly developing rash, a haemorrhagic diathesis, multisystem failure and age over 60 years.

**Prevention of meningococcal infection**

Close contacts of patients with meningococcal infection (Box 28.64) should be given a single dose of ciprofloxacin. Rifampicin for two days is an alternative for those unable to take ciprofloxacin. If not treated with ceftriaxone or cefotaxime, the index case should be given similar treatment to clear infection from the nasopharynx before hospital discharge. Vaccines are available for most meningococcal subgroups.

---

**Fig. 28.33 The investigation of meningitis based on the British Infection Association acute meningitis guideline.** (CRP = C-reactive protein; GCS = Glasgow Coma Scale; LP = lumbar puncture; PCR = polymerase chain reaction) (Adapted from the UK joint specialist societies guideline on the diagnosis and management of acute meningitis and meningococcal sepsis in immunocompetent adults. *Journal of Infection* 2016; 72: 405–438.)

---

1. **Adults aged less than 60 years**
   - Cefotaxime 2 g IV 4 times daily or
   - Ceftriaxone 2 g IV twice daily

2. **Patients in whom penicillin-resistant pneumococcal infection is suspected, or in areas with a significant incidence of penicillin resistance in the community**
   As for (1) but add:
   - Vancomycin 15–20 mg/kg IV twice daily or
   - Rifampicin 600 mg IV or orally twice daily

3. **Adults aged >60 years and those in whom *Listeria monocytogenes* infection is suspected (brainstem signs, immunosuppression, diabetic, alcohol misuser)**
   As for (1) but add:
   - Amoxicillin 2 g IV 6 times daily or
   - Amoxicillin 2 g IV 6 times daily

4. **Adults aged >60 years, or with risk factors in (3) above, in areas with a significant incidence of penicillin resistance in the community**
   As for (2) but add:
   - Amoxicillin 2 g IV 6 times daily or
   - Amoxicillin 2 g IV 6 times daily

5. **Patients with a clear history of anaphylaxis to β-lactams**
   - Chloramphenicol 25 mg/kg IV 4 times daily plus
   - Vancomycin 15–20 mg/kg IV twice daily
   If over the age of 60 years, add: co-trimoxazole 10–20 mg/kg (of the trimethoprim component) in four divided doses

6. **Adjunctive treatment (see text)**
   - Dexamethasone 10 mg 4 times daily for 2–4 days

*N.B. Antibiotic recommendations depend on local epidemiology of organisms and antibiotic resistance. Local guidance should always be sought.

Tuberculous meningitis

Tuberculous meningitis is now uncommon in high-income countries except in immunocompromised individuals, although it is still seen in those born in endemic areas and in low- and middle-resource countries. It is seen more frequently as a secondary infection in patients with HIV infection.

Pathophysiology

Tuberculous meningitis most commonly occurs shortly after a primary infection in childhood or as part of miliary tuberculosis. The usual local source of infection is a caseous focus in the meninges or brain substance adjacent to the CSF pathway. The brain is covered by a greenish, gelatinous exudate, especially around the base, and numerous scattered tubercles are found on the meninges.

Clinical features

The clinical features and staging criteria are listed in Box 28.65. Onset is much slower than in other bacterial meningitis — over 2–8 weeks. If untreated, tuberculous meningitis is fatal in a few weeks but complete recovery is usual if treatment is started at stage I (Box 28.65). When treatment is initiated later, the rate of death or serious neurological deficit may be as high as 30%.

Investigations

Lumbar puncture should be performed if the diagnosis is suspected. The CSF is under increased pressure. It is usually clear but, when allowed to stand, a fine clot (‘spider web’) may form. The fluid contains up to 500 x10^6 cells/μL, predominantly lymphocytes, but can contain neutrophils. There is a rise in protein, often marked, and a similarly marked fall in glucose. The tubercle bacillus may be detected in a smear of the centrifuged deposit from the CSF but a negative result does not exclude the diagnosis. The CSF should be cultured but, as this result will not be known for up to 6 weeks, treatment must be started without waiting for confirmation. The WHO recommends use of additional nucleic acid amplification tests (NAATs), specifically Xpert MTB/RIF Ultra. This should be used in addition to smear and culture studies, as NAATs are not sensitive enough to exclude tuberculous meningitis when negative. Brain imaging may show hydrocephalus, brisk particularly basal meningeal enhancement on enhanced CT or MRI, and/or uncommonly an intracranial tumour.

Management

As soon as the diagnosis is made or strongly suspected, chemotherapy should be started using one of the regimens that include pyrazinamide, described on page 522. The use of glucocorticoids in addition to antituberculous therapy has been controversial. Recent evidence suggests that it improves mortality, especially if given early, but not focal neurological damage whether associated with HIV infection or not. Surgical
ventricular drainage may be needed if obstructive hydrocephalus develops. Skilled nursing is essential during the acute phase of the illness, and adequate hydration and nutrition must be maintained.

### Fungal meningitis

Fungal meningitis is uncommon and usually occurs in the immunosuppressed. The yeast Cryptococcus neoformans is the commonest and an important cause of meningitis in those immunosuppressed by HIV infection. It does occur in the immunocompetent although non-HIV forms of immunocompromise should be sought. The presentation may be atypical with subacute or chronic meningitis, fever, headache and symptoms of raised intracranial pressure occur. The CSF opening pressure is often very raised, with 20–200 cells x10^3/L mainly lymphocytes, elevated protein and low glucose levels (similar to findings in tuberculous meningitis) (Box 28.6). In some regions the India ink test and cryptococcal PCR are used to detect cryptococci in the CSF. Cryptococcal antigen is present in the CSF and sometimes serum. Treatment is discussed on p. 363. Treatment of raised CSF pressure may be complex and frequent, sometimes daily, lumbar punctures are required.

### Other meningitides

In some areas, meningitis may be caused by spirochaetes (l Typhus, Lyme disease and syphilis; rickettsiae (typhus fever) or protozoa (primary amoebic meningocerebral, PAM).

Meningitis can also be due to non-infective pathologies. This is seen in recurrent aseptic meningitis resulting from systemic lupus erythematosus (SLE), Behçet’s disease or sarcoidosis, as well as a condition of previously unknown origin known as Mollaret syndrome, in which the recurrent meningitis is associated with epithelial cells in the spinal fluid (Mollaret cells). Recent evidence suggests that this condition may be due to herpes simplex virus type 2 and is therefore infective after all. Meningitis can also be caused by direct invasion of the meninges by neoplastic cells (“malignant meningitis”; see Box 28.59).

### Subdural empyema

This is a rare complication of frontal sinusitis, osteomyelitis of the skull vault or middle ear disease. A collection of pus in the subdural space spreads over the surface of the hemisphere, causing underlying cortical oedema or thombophlebitis. Patients present with severe pain in the face or head and pyrexia, often with a history of preceding paranasal sinus or ear infection. The patient then becomes drowsy, with seizures and focal signs such as a progressive hemiparesis.

The diagnosis rests on a strong clinical suspicion in patients with a local focus of infection. Careful assessment with contrast-enhanced CT or MRI may show a subdural collection with underlying cerebral oedema. Management requires aspiration of pus via a burr hole and appropriate parental antibiotics. Any local source of infection must be treated to prevent re-infection.

### Spinal epidural abscess

The characteristic clinical features are back pain, often in a nerve root distribution and progressive transverse spinal cord syndrome with paraparesis, sensory impairment and sphincter dysfunction. There may be fever and raised inflammatory markers. Features of the primary focus of infection may be less obvious and thus can be overlooked. The resurgence of resistant staphylococcal infection and injection drug use has contributed to a recent marked rise in incidence.

Once the diagnosis is suspected, an MRI scan of the spine should be carried out (or myelography if MRI is not available). MRI is often negative in early disease, so if it is non-diagnostic and the clinical suspicion remains, it should be repeated after a week or so. Obtaining a bacteriological diagnosis is a high priority, and antibiotics are not usually started until this has been achieved (or at least attempted), e.g. by blood culture and tissue aspiration or biopsy. If there is spinal cord compression surgical treatment is required (e.g. decompressive laminectomy with abscess drainage). However, in the absence of neurological impairment, treatment with antibiotics alone is often attempted, usually using intravenous antibiotics for at least 6 weeks, guided by clinical and biochemical response.

### Parenchymal viral infections

Infection of the substance of the nervous system will produce symptoms of focal dysfunction (deficits and/or seizures) with general signs of infection, depending on the acuteness of the infection and the type of organism.

### Viral encephalitis

A range of viruses can cause encephalitis but only a minority of patients report recent systemic viral infection (Box 28.66). The relative importance of specific viruses depends on location and the specific population involved, e.g. immunosuppressed. In high-income countries, the most serious cause of viral encephalitis is herpes simplex, which probably reaches the brain via the olfactory nerves. The development of effective therapy for some forms of encephalitis has increased the importance of clinical diagnosis and virological examination of the CSF.

#### Pathophysiology

The infection provokes an inflammatory response that involves the cortex, white matter, basal ganglia and brainstem. The distribution of lesions varies with the type of virus. For example, in herpes simplex encephalitis, the temporal lobes are usually primarily affected, whereas cytomegalovirus can involve the areas adjacent to the ventricles (ventriculitis). Inclusion bodies may be present in the neurons and glial cells, and there is an infiltration of polymorphonuclear cells in the plexiformal space. There is neuronal degeneration and diffuse glial proliferation, often associated with cerebral oedema.

#### Clinical features

Viral encephalitis presents with acute onset of headache, fever, focal neurological signs (aphasia and/or hemiplegia, visual field defects) and seizures. Disturbance of consciousness ranging from drowsiness to deep coma supervenes early and may advance dramatically. Meningism occurs in many patients. Additional clues to the causative virus are listed in Box 28.66. Rabies presents a distinct clinical picture and is described below.

#### Investigations

Imaging by CT scan may show low-density lesions in the temporal lobes but MRI is more sensitive in detecting early abnormalities. Lumbar puncture should be performed once imaging has excluded a mass lesion. The CSF usually contains excess lymphocytes but polymorphonuclear cells may predominate in the early stages. The CSF may be normal in up to 10% of cases. Some viruses, including the West Nile virus, may cause a sustained neutrophilic CSF. The protein content may be elevated but the glucose is normal. The EEG is usually abnormal in the early stages, especially in herpes simplex encephalitis, with characteristic periodic slow-wave activity in the temporal lobes. Virological investigations of the CSF, including PCR, may reveal the causative organism but treatment initiation should not await this.

#### Management

Optimum treatment for herpes simplex encephalitis (aciclovir 10 mg/kg IV 3 times daily for 2–3 weeks) has reduced mortality from 70% to around 10%. This should be given early to all patients suspected of having viral encephalitis.

Some survivors will have residual epilepsy or cognitive impairment. For details of post-infectious encephalomyelitis, see page 1163. Antiepileptic treatment may be required and raised intracranial pressure may indicate the need for dexamethasone.

(MRI = magnetic resonance imaging)

### Brainstem encephalitis

This presents with ataxia, dysarthria, diplopia or other cranial nerve palsies. The CSF is lymphocytic, with a normal glucose. The causative agent is presumed to be viral. However, *Listeria monocytogenes* may cause a similar syndrome with meningitis (and often a polymorphonuclear CSF pleocytosis) and requires specific treatment with ampicillin (2 grams 6 times daily; see Box 28.63).

### Rabies

Rabies is caused by a rhabdovirus that infects the central nervous tissue and salivary glands of a wide range of mammals. It is usually conveyed by saliva through bites or licks on abrasions or on intact mucous membranes. Humans are most frequently infected from dogs and bats. In Europe, the maintenance host is the fox. The incubation period varies in humans from a minimum of 9 days to many months but is usually between 4 and 8 weeks. Severe bites, especially if on the head or neck, are associated with shorter incubation periods. Human rabies is a rare disease, even in endemic areas. However, because it is usually fatal, major efforts are directed at limiting its spread and preventing its importation into uninfected countries, such as the UK.

### Clinical features

At the onset there may be fever, and paraesthesia at the site of the bite. A prodromal period of 1–10 days, during which the patient becomes increasingly anxious, leads to the characteristic ‘hydrophobia’. Although the patient is thirsty, attempts at drinking provoke violent contractions of the diaphragm and other inspiratory muscles. Delusions and hallucinations may develop, accompanied by spitting, biting and mania, with lucid intervals in which the patient is markedly anxious. Cranial nerve lesions develop and terminal hyperpyrexia is common. Death ensues, usually within a week of the onset of symptoms.

### Investigations

During life, the diagnosis is usually made on clinical grounds but rapid immunofluorescent techniques can detect antigen in corneal impression smears or skin biopsies.
Management

Established disease

Only a few patients with established rabies have survived. All received some post-exposure prophylaxis (see below) and needed intensive care facilities to control cardiac and respiratory failure. Otherwise, only palliative treatment is possible once symptoms have appeared. The patient should be heavily sedated with diazepam, supplemented by chlorpromazine if needed. Nutrition and fluids should be given intravenously or through a gastrostomy.

Pre-exposure prophylaxis

Pre-exposure prophylaxis with rabies vaccine is required by those who handle potentially infected animals professionally, work with rabies virus in laboratories or live at special risk in rabies-endemic areas.

Post-exposure prophylaxis

The wounds should be thoroughly cleaned, preferably with a quaternary ammonium detergent or soap; damaged tissues should be excised and the wound left unsutured. Rabies can usually be prevented if treatment is started within a day or two of biting. Delayed treatment may still be of value. For maximum protection, hyperimmune serum and vaccine are required.

The safest anti-rabies antiserum is human rabies immunoglobulin. The dose is 20 IU/kg body weight; half is infiltrated around the bite and half is given intramuscularly at a different site from the vaccine. Hyperimmune animal serum may be used but hypersensitivity reactions, including anaphylaxis, are common.

The safest vaccine, free of complications, is human diploid cell strain vaccine. Post-exposure treatment is complex and depends on a composite risk based on the risk by country and the category of exposure. Detailed advice may be available locally or on the UK website https://www.gov.uk/government/publications/rabies-post-exposure-prophylaxis-management-guidelines. For example, an unvaccinated individual from a high-risk country exposed to direct contact with terrestrial mammal saliva should receive human rabies immunoglobulin and four doses of vaccine on days 0, 3, 7 and 21. If immunocompromised, they should receive five doses of vaccine on days 0, 3, 7, 14 and 30. In contrast, an individual in a low-risk country and no physical contact with terrestrial mammal saliva would not require post-exposure prophylaxis.

Human immunodeficiency virus (HIV) infection

Box 28.67 summarises the neurological manifestations of HIV infection. These are covered in detail in Chapter 14.

Poliomyelitis

Disease is caused by one of three polioviruses, which constitute a subgroup of the enteroviruses. Poliomyelitis has become much less common following the introduction of the Global Polio Eradication initiative. Incidence dropped from more than 350,000 cases in 1988 to 33 in 2018. However, incomplete immunisation still results in small numbers of cases. Transmission usually occurs through faecal–hand–oral contamination with primary replication in the lymphatic tissue of the gastrointestinal and oropharyngeal tracts.

The virus causes a lymphocytic meningitis and infects the grey matter of the spinal cord, brainstem and cortex. There is a particular propensity to damage anterior horn cells, especially in the lumbar segments.

Many patients recover fully after the initial phase of a few days of mild fever and headache. In other individuals, after a week of well-being, there is a recurrence of pyrexia, headache and meningism. Weakness may start later in one muscle group and can progress to widespread paraparesis. Respiratory failure may supervene if intercostal muscles are paralysed or the medullary motor nuclei are involved. Poliomyelitis virus may be cultured from CSF and stool. Second attacks are very rare but occasionally patients show late deterioration in muscle bulk and power many years after the initial infection (this is termed the ‘post-polio syndrome’).

Prevention of poliomyelitis is by immunisation with live Sabin vaccine, a collection of live attenuated polio viruses (OPV – oral polio virus vaccine) in low- and middle-income regions. The advantages of OPV include cost, ease of administration and transmission of the vaccine virus to unimmunised contacts. In high-income countries where polio is now very rare, the live vaccine has been replaced by the Salk vaccine (iPV), a collection of inactivated polio viruses. Advantages include avoidance of vaccine-associated paralytic poliomyelitis and effective combination with other routine childhood vaccines.

Herpes zoster (shingles)

Herpes zoster is the result of reactivation of the varicella zoster virus that has lain dormant in a nerve root ganglion following chickenpox earlier in life. Reactivation may be spontaneous (as usually occurs in middle-aged or older adults) or due to immunosuppression (as in patients with diabetes, malignant disease or HIV).
Subacute sclerosing panencephalitis

This is a rare, chronic, progressive and eventually fatal complication of measles, presumably a result of an inability of the nervous system to eradicate the virus. It occurs in children and adolescents, usually many years after the primary virus infection. There is generalised neurological deterioration and onset is insidious, with intellectual deterioration, apathy and clumsiness, followed by myoclonic jerks, rigidity and dementia.

The CSF may show a mild lymphocytic pleocytosis and the EEG demonstrates characteristic periodic bursts of triphasic waves. Although there is persistent measles-specific IgG in serum and CSF, antiviral therapy is ineffective and death ensues within a few years.

Progressive multifocal leuencephalopathy

This was originally described as a rare complication of lymphoma, leukaemia or carcinomatosis but is seen in untreated HIV/AIDS or secondary to immunosuppression, e.g. following organ transplantation or use of disease-modifying drugs for MS, in particular natalizumab. It is an infection of oligodendrocytes and other neural cells by human polyomavirus JC, causing widespread demyelination of the white matter of the cerebral hemispheres. Clinical signs include dementia, hemiparesis and aphasia, which progress rapidly, usually leading to death within weeks or months. Areas of low density in the white matter are seen on CT but MRI is more sensitive, showing diffuse high signal in the cerebral white matter on T2-weighted images, sometimes with contrast enhancement. The only treatment available is restoration of the immune response (by treating HIV/AIDS or reversing immunosuppression) which can lead to the development of an immune reconstitution inflammatory syndrome (PML-IRIS).

Parenchymal bacterial infections

Cerebral abscess

Bacteria may enter the cerebral substance through penetrating injury, by direct spread from paranasal sinuses or the middle ear, or secondary to sepsis. Untreated congenital heart disease is a recognised risk factor. The site of abscess formation and the likely causative organism are both related to the source of infection (Box 28.68). Initial infection leads to local suppuration followed by loculation of pus within a surrounding wall of glialis, which in a chronic abscess may form a tough capsule. Haematogenous spread may lead to multiple abscesses.

Clinical features

A cerebral abscess may present acutely with fever, headache, meningism and drowsiness, but more commonly presents over days or weeks as a cerebral mass lesion with little or no evidence of infection. Seizures, raised intracranial pressure and focal headache signs occur alone or in combination. Distinction from a cerebral tumour may be impossible on clinical grounds.

Investigations

Lumbar puncture is potentially hazardous in the presence of raised intracranial pressure and CT should always precede it. CT reveals single or multiple low-density areas, which show ring enhancement with contrast and surrounding cerebral oedema (Fig. 28.34). There may be an elevated white blood cell count and ESR in patients with acute local infection. The possibility of cerebral toxoplasmosis or tuberculous disease secondary to HIV infection should always be considered. MRI with diffusion weighted imaging may be helpful in distinguishing between cerebral abscess (hyperintense) and tumour (hypointense or variable increase lower than found in abscess).

Management and prognosis

Antimicrobial therapy is indicated once the diagnosis is made. The likely source of infection should guide the choice of antibiotic (see Box 28.68).

Surgical drainage by burr-hole aspiration or excision may be necessary, especially where the presence of a capsule may lead to a persistent focus of infection. Epilepsy frequently develops and is often resistant to treatment.

Despite advances in therapy, mortality remains 10%–20% and may partly relate to delay in diagnosis and treatment.

Lyme disease

Infection with Borrelia burgdorferi can cause numerous neurological problems, including polyradiculopathy, meningitis, encephalitis and mononeuritis multiplex.

Neurosyphilis

Neurosyphilis may present as an acute or chronic process and may involve the meninges, blood vessels and/or parenchyma of the brain and spinal cord. The decade to 2008 saw a 10-fold increase in the incidence of syphilis. The clinical manifestations are diverse and early diagnosis and treatment are essential.

Clinical features

The clinical and pathological features of the three most common presentations are summarised in Box 28.69. Neurological examination reveals signs indicative of the anatomical localisation of lesions. Delusions of grandeur suggest general paresis of the insane, but more commonly there is simply progressive dementia. Small and irregular pupils that react to convergence but not light, as described by Argyll Robertson (see Box 28.21), may accompany any neurosyphilitic syndrome but most commonly tabes dorsalis.

Investigations

Routine screening for syphilis is warranted in many neurological patients. Treponemal antibodies are positive in the serum in most patients, but
CSF examination is essential if neurological involvement is suspected. Active disease is suggested by an elevated cell count, usually lymphocytic, and the protein content may be elevated to 0.5–1.0 g/L. Serological tests in CSF are usually positive but progressive disease can occur with negative CSF serology.

**Management**

Aqueous crystalline penicillin G intravenously or intramuscular injection of procaine benzylpenicillin (procaine penicillin) and probenecid for 10–14 days is essential in the treatment of neurosyphilis of all types. Further courses of penicillin must be given if symptoms are not relieved, if the condition continues to advance or if the CSF continues to show signs of active disease. The cell count returns to normal within 3 months of completion of treatment, but the elevated protein takes longer to subside and some serological tests may never revert to normal. Evidence of clinical progression at any time is an indication for renewed treatment.

The spinal cord can be involved by other infections, including HTLV1, TB, bilharzia and echinococcus.

### Parenchymal parasitic infections

#### Neurocysticercosis

Neurocysticercosis is the commonest parasitic neurological disease globally. Most infections occur in low-resource regions, but it occurs in high-resource regions in travellers and immigrants. Cysts may be asymptomatic, often for years, or symptomatic, the symptoms depending on the site of the cysts. Seizures are the commonest manifestation. Parenchymal cysts occur in the brain or in the convexity sulci, while extraparenchymal cysts occur in the ventricles, cisterns and the spinal cord, and present most often with raised intracranial pressure. Investigation and management are discussed on p. 342.

#### Cerebral malaria

Cerebral malaria should be suspected in anyone presenting with fever, altered awareness or behaviour living in or returning from travel to a malaria endemic area. Drowsiness may progress over a few days, but coma can occur within hours. Level of consciousness may fluctuate and seizures occur, but focal neurological signs are unusual. The eyes frequently diverge with roving eye movements, but cranial nerve involvement and papilloedema are uncommon and suggest other causes, e.g. meningitis. Cerebral malaria is a serious condition with a case fatality rate of 15%–20% and requires rapid diagnosis and treatment (see Box 13.56).

#### Neuroschistosomiasis

Schistosomiasis is commonest in sub-Saharan Africa and neuroschistosomiasis should be considered in individuals in endemic areas and returning travellers presenting with neurological signs. The brain, but more commonly spine (particularly conus medullaris) and cauda equina can be involved. Spinal cord involvement often results in a rapidly progressive transverse myelitis, leg pain, bladder and bowel involvement. Investigation and management are discussed on p. 338.
Parenchymal fungal infections

Fungal infections of brain parenchyma are uncommon but occur particularly in the immunocompromised, in the presence of intraventricular devices and as an extension of sinus infection.

Diseases caused by bacterial toxins

Tetanus

This disease results from infection with Clostridium tetani, a commensal in the gut of humans and domestic animals that is found in soil. Infection enters the body through wounds, which may be trivial. It is rare in the UK, occurring mostly in gardeners and farmers, but a recent increase has been seen in injection drug users. By contrast, the disease is common in many countries, where dust contains spores derived from animal and human excreta. Unhygienic practices soon after birth may lead to infection of the umbilical stump or site of circumcision, causing tetanus neonatorum. Tetanus is still one of the major killers of adults, children and neonates in low-income countries, where the mortality rate can be nearly 100% in the newborn and around 40% in others.

In circumstances unfavourable to growth of the organism, spores are formed and these may remain dormant for years in the soil. Spores germinate and bacilli multiply only in the anaerobic conditions that occur in areas of tissue necrosis or if the oxygen tension is lowered by the presence of other organisms, particularly if aerobic. The bacilli remain localised but produce an exotoxin with an affinity for motor nerve endings and motor nerve cells.

The anterior horn cells are affected after the exotoxin has passed into the bloodstream and their involvement results in rigidity and convulsions. Symptoms first appear from 2 days to several weeks after injury: the shorter the incubation period, the more severe the attack and the worse the prognosis.

Clinical features

By far the most early symptom is trismus – spasm of the masseter muscles, which causes difficulty in opening the mouth and in masti cating; hence the name ‘lockjaw’. Lockjaw in tetanus is painless, unlike the spasm of the masseters due to dental abscess, septic throat or other causes. Conditions that can mimic tetanus include functional neurological disorders and phenothiazine overdosage, or overdose in injection drug users.

In tetanus, the tonic rigidity spreads to involve the muscles of the face, neck and trunk. Contraction of the frontalis and the muscles at the angles of the mouth leads to the so-called ‘risus sardonicus’. There is rigidity of the muscles at the neck and trunk of varying degree. The back is usually slightly arched (‘opisthotonus’) and there is a board-like abdominal wall.

In the more severe cases, violent spasms lasting for a few seconds to 3–4 minutes occur spontaneously, or may be induced by stimuli such as movement or noise. These episodes are painful and exhausting, and suggest a grave outlook, especially if they appear soon after the onset of symptoms. They gradually increase in frequency and severity for about 1 week and the patient may die from exhaustion, asphyxia or aspiration pneumonia. In less severe illness, periods of spasm may not commence until a week or so after the first sign of rigidity, and in very mild infections they may never appear. Autonomic involvement may cause cardiovascular complications, such as hypertension. Rarely, the only manifestation of the disease may be ‘local tetanus’ – stiffness or spasm of the muscles near the infected wound – and the prognosis is good if treatment is commenced at this stage.

Investigations

The diagnosis is made on clinical grounds. Laboratory testing supports the diagnosis, but treatment should not be delayed while waiting for results. Wound tissue samples or a wound swab may be sent in cooked meat broth for PCR and culture of C. tetani. Serum samples should be collected, before immunoglobulin is given, for tetanus toxin and antibodies against tetanus toxoid.

Management

Established disease

Management of established disease should begin as soon as possible, as shown in Box 28.70.

Prevention

Tetanus can be prevented by immunisation and prompt treatment of contaminated wounds by débridement and antibiotics. In patients with a contaminated wound, a 7–10-day course of metronidazole (500 mg intravenously every 6–8 hours) or penicillin G (2–4 million units every 4–6 hours) are recommended. Alternative antibiotics include tetracyclines, macrolides, clindamycin, cephalosporins and chloramphenicol. Tetanus toxoid containing vaccine and human tetanus immunoglobulin use should follow local guidelines, and depend on the level of risk associated with a wound, prior immunisation and time since last tetanus vaccination.

Botulism

Botulism is caused by the neurotoxins of Clostridium botulinum, which are extremely potent and cause disease after ingestion of even picogram amounts. Its classical form is an acute onset of bilateral cranial neuropathies associated with symmetric descending weakness.

Anaerobic conditions are necessary for the organism’s growth. It may contaminate and thrive in many foodstuffs, where sealing and preserving provide the requisite conditions. Contaminated honey has been implicated in infant botulism, in which the organism colonises the gastrointestinal tract. Wound botulism is a growing problem in injection drug users.

The toxin causes predominantly bulboc and ocular palsies (difficulty in swallowing, blurred or double vision, ptosis), progressing to limb weakness and respiratory paralysis. Criteria for the clinical diagnosis are shown in Box 28.71.

Management includes assisted ventilation and general supportive measures until the toxin eventually dissipates from nerve endings 6–8 weeks following ingestion. A polyvalent antitoxin is available for

28.70 Treatment of tetanus (consult local guidance)

Neutralise absorbed toxin

- Human tetanus antitoxin IM/N (local guidance varies) or where human tetanus antitoxin is not available (e.g. in the UK), IVG (human intravenous immunoglobulin) IV*

Prevent further toxin production

- Débride wound
- Give metronidazole 500 mg IV every 6–8 hours ideally, or penicillin G 2–4 million units IV every 4–6 hours for 7–10 days

Control spasms

- Nurse in a quiet room
- Avoid unnecessary stimuli
- Give IV diazepam
- If spasms continue, paralyse patient and ventilate

General measures

- Maintain hydration and nutrition
- Treat secondary infections
- Vaccination following recovery

(M = intramuscular; N = intravenous)
post-exposure prophylaxis and for the treatment of suspected botulism. It specifically neutralises toxin types A, B and E and is not effective against infant botulism (in which active growth of the organism allows continued toxin production).

Prion diseases

Prions are unique amongst infectious agents in that they are devoid of any nucleic acid. They appear to be transmitted by acquisition of a normal mammalian protein (prion protein, PrP\(^{c}\)) that is in an abnormal conformation (PrP\(^{sc}\), containing an excess of beta-sheet protein). The result is accumulation of protein that forms amyloid in the CNS, causing a transmissible spongiform encephalopathy (TSE) across several species.

Human prion diseases (Box 28.72) are characterised by the histopathological triad of cortical spongiform change, neuronal cell loss and gliosis. Associated with these changes there is deposition of amyloid, made up of an altered form of a normally occurring protein, the prion protein. Prion proteins are not inactivated by cooking or conventional sterilisation, and transmission is thought to occur by consumption of infected CNS tissue or by inoculation (e.g. via depth EEG electrodes, corneal grafts, cadaveric dura mater grafts and pooled cadaveric growth hormone preparations). The same diseases can occur in an inherited form, due to mutations in the PrP gene.

The apparent transmission of bovine spongiform encephalopathy (BSE) to humans was thought to be responsible for the emergence of a new variant of Creutzfeldt–Jakob disease (vCJD) in the UK (see below). This outbreak led to nationwide precautionary measures, such as leukodepletion of all blood used for transfusion, and the mandatory use of disposable surgical instruments wherever possible for tonsillectomy, appendicectomy and ophthalmological procedures.

### Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is the best-characterised human TSE. Some 10% of cases arise from a mutation in the gene coding for the prion protein. The sporadic form is the most common, occurring in middle-aged to older patients. Clinical features usually involve a rapidly progressive dementia, with myoclonus and a characteristic EEG pattern (repetitive slow-wave complexes), although a number of other features, such as visual disturbance or ataxia, may also be seen. These are particularly common in CJD transmitted by inoculation (e.g. by infected dura mater grafts). Death occurs after a mean of 4–6 months. There is no effective treatment.

### Variant Creutzfeldt–Jakob disease

This type of CJD (vCJD) emerged in the late 1990s, affecting a small number of patients in the UK. The causative agent appears to be identical to that causing BSE in cows, and the disease may have been a result of the epidemic of BSE in the UK a decade earlier. Patients affected by vCJD are typically younger than those with sporadic CJD and present with neuropsychiatric changes and sensory symptoms in the limbs, followed by ataxia, dementia and death. Progression is slightly slower than in patients with sporadic CJD (mean time to death is over a year). Characteristic EEG changes are not present, but MRI brain scans show typical high-signal changes in the pulvinar thalami in a high proportion of cases (Fig. 28.35). Brain histology is distinct, with very florid plaques containing the prion proteins. Abnormal prion protein has been identified in tonsillar specimens from patients with vCJD, leading to the suggestion that the disease could be transmitted by reticulo-endothelial tissue (like TSEs in animals but unlike sporadic CJD in humans). It was the emergence of this form of the disorder that led to the changes in public health and farming policy in the UK; while the incidence of vCJD has declined dramatically, surveillance and research continue.
28.73 Common causes of raised intracranial pressure

**Mass lesions**
- Intracranial haemorrhage (traumatic or spontaneous):
  - Extrudural haematoma
  - Subdural haematoma
  - Intraaxial (intracerebral) haemorrhage
- Cerebral tumour (particularly posterior fossa lesions or high-grade gliomas: see Box 28.75)
- Infective:
  - Cerebral abscess
  - Tuberculosis
  - Osteomyelitis
  - Hydatid cyst
- Colloid cyst (in ventricles)

**Disturbance of cerebrospinal fluid circulation**
- Obstructive (non-communicating) hydrocephalus: obstruction within ventricular system
- Communicating hydrocephalus: site of obstruction outside ventricular system

**Obstruction to venous sinuses**
- Cerebral venous thrombosis
- Trauma (depended fractures overlying sinuses)

**Diffuse brain oedema or swelling**
- Meningo-encephalitis
- Trauma (diffuse head injury, near-drowning)
- Subarachnoid haemorrhage
- Metabolic (e.g. water intoxication)
- Idiopathic intracranial hypertension

#### Intracranial mass lesions and raised intracranial pressure

Many different types of mass lesion may arise within the intracranial cavity (Box 28.73). In low-income countries tuberculosis and other infections are frequent causes, but in the West intracranial haemorrhage and brain tumours are more common. The clinical features depend on the site of the mass, its nature and its rate of expansion. Symptoms and signs (see Box 28.74) are produced by a number of mechanisms.

#### Raised intracranial pressure

Raised intracranial pressure (RICP) may be caused by mass lesions, cerebral oedema, obstruction to CSF circulation leading to hydrocephalus, impaired CSF absorption and cerebral venous obstruction (see Box 28.73).

**Clinical features**

In adults, intracranial pressure is less than 10–15 mm Hg. The features of RICP are listed in Box 28.74. The speed of pressure increase influences presentation. If it is slow, compensatory mechanisms may occur, including alteration in the volume of fluid in CSF spaces and venous sinuses, minimising symptoms. Rapid pressure increase (as in aggressive tumours) does not permit these compensatory mechanisms to take place, leading to early symptoms, including sudden death. Papilloedema is not always present, either because the pressure rise has been too rapid or because of anatomical anomalies of the meningeal sheath of the optic nerve.

A false localising sign is one in which the pathology is remote from the site of the expected lesion; in RICP, the 6th cranial nerve (unilateral or bilateral) is most commonly affected but the 3rd, 5th and 7th nerves may also be involved. Sixth nerve palsies are thought to be due either to stretching of the long slender nerve or to compression against the petrous temporal bone ridge. Tentorial herniation of the uncus may compress the ipsilateral 3rd nerve and usually involves the pupillary fibres first, causing a dilated pupil; however, a false localising contralateral 3rd nerve palsy may also occur, perhaps due to extrinsic compression by the tentorial margin. Vomiting, coma, bradycardia and arterial hypertension are later features of RICP.

The rise in intracranial pressure from a mass lesion may cause displacement of the brain. Downward displacement of the medial temporal lobe (uncus) through the tentorium due to a large hemisphere mass may cause “temporal coning” (Fig. 28.36). This may stretch the 3rd and/or 6th cranial nerves or cause pressure on the contralateral cerebral peduncle (giving rise to ipsilateral upper motor neuron signs) and is usually accompanied by progressive coma. Downward movement of the cerebellar tonsils through the foramen magnum may compress the medulla – “tonsillar coning” (Fig. 28.37). This may result in brainstem haemorrhage and/or acute obstruction of the CSF pathways. As coning progresses, coma and death occur unless the condition is rapidly treated.
Management

Primary management of RICP should be targeted at relieving the cause (e.g. surgical decompression of mass lesion, glucocorticoids to reduce vasogenic oedema or shunt procedure to relieve hydrocephalus). Supportive treatment includes maintenance of fluid balance, blood pressure control, head elevation and use of diuretics such as mannitol. Intensive care support may be needed.

Brain tumours

Primary brain tumours are a heterogeneous collection of neoplasms arising from the brain tissue or meninges and vary from benign to highly malignant. Primary malignant brain tumours (Box 28.75) are rare, accounting for 1% of all adult tumours but a higher proportion in children. The most common benign brain tumour is a meningioma. Primary brain tumours do not metastasise due to the absence of lymphatic drainage in the brain. There are rare pathological subtypes, however, such as medulloblastoma, which do have a propensity to metastasise; the reasons for this are not clear. Most cerebral tumours are sporadic but may be associated with genetic syndromes such as neurofibromatosis or tuberous sclerosis. Brain tumours are not classified by the usual TNM system but by the World Health Organization (WHO) grading I–IV; this is based on histology (e.g. nuclear pleomorphism, presence of mitoses and presence of necrosis), with grade I the most benign and grade IV the most malignant. Glomas account for 60% of brain tumours, with the aggressive glioblastoma multiforme (WHO grade IV) the most common glioma, followed by meningiomas (20%) and pituitary tumours (10%). Although the lower-grade gliomas (I and II) may be very indolent, with prognosis measured in terms of many years, these may transform to higher-grade disease at any time, with a resultant sharp decline in life expectancy.

Most malignant brain tumours are due to metastases, with intracranial metastases complicating about 20% of extracranial malignancies. The rate is higher with primaries in the bronchus, breast and gastrointestinal tract (Fig. 28.38). Metastases usually occur in the white matter of the cerebral or cerebellar hemispheres but there are diffuse leptomeningeal types.

Clinical features

The presentation is variable and usually influenced by the rate of growth. High-grade disease (WHO grades III and IV) tends to present with a short (weeks) history of mass effect (headache, nausea secondary to RICP), while more indolent tumours can present with slowly progressive focal neurological deficits, depending on their location (see Box 28.74); generalised or focal seizures are common in either. Headache, if present, is usually accompanied by focal deficits or seizures, and isolated stable headache is almost never due to intracranial tumour.

The size of the primary tumour is of far less prognostic significance than its location within the brain. Tumours within the brainstem will result in early neurological deficits, while those in the frontal region may be quite large before symptoms occur.

Investigations

Diagnosis is by neuroimaging (Figs. 28.39 and 28.40) and pathological grading following biopsy or resection where possible. The more malignant tumours are more likely to demonstrate contrast enhancement on imaging. If the tumour appears metastatic, further investigation to find the primary is required.
Management

Brain tumours are treated with a combination of surgery, radiotherapy and chemotherapy, depending on the type of tumour and the patient. Advancing age is the most powerful negative prognostic factor in CNS tumours, so best supportive care (including glucocorticoid therapy) may be most appropriate in older patients with metastases or high-grade disease. Treatment may not always be indicated in low-grade gliomas and watchful waiting may be appropriate, although a more aggressive approach is increasingly favoured.

Dexamethasone given orally (or intravenously where RICP is acutely or severely raised) may reduce the vasogenic oedema typically associated with metastases and high-grade gliomas.

Prolactin- or growth hormone-secreting pituitary adenomas may respond well to treatment with dopamine agonists (such as bromocriptine, cabergoline or quinagolide); in this situation, imaging and hormone levels may be all that is required to establish a formal diagnosis, precluding the need for surgery.

Surgical

The mainstay of primary treatment is surgery, either resection (full or partial debulking) or biopsy, depending on the site and likely radiological diagnosis. Clearly, if a tumour occurs in an area of brain that is highly important for normal function (e.g., motor strip), then biopsy may be the only safe surgical intervention but, in general, maximal safe resection is the optimal surgical management. Meningiomas and acoustic neuromas offer the best prospects for complete removal and thus cure. Some meningiomas can recur, however, particularly those of the sphenoid ridge, when partial excision is often all that is possible. Thereafter, post-operative surveillance may be required, as radiotherapy is effective at preventing further growth of residual tumour. Pituitary adenomas may be removed by a trans-sphenoidal route, avoiding the need for a craniotomy. Unfortunately, gliomas, which account for the majority of brain tumours, cannot be completely excised, since infiltration spreads well beyond the apparent radiological boundaries of the intracranial mass. Recurrence is therefore the rule, even if the mass of the tumour is apparently removed completely; partial excision (“debulking”) may be useful in alleviating symptoms caused by RICP but although there is increasing evidence that the degree of surgical excision may have a positive influence on survival, this has not yet been convincingly demonstrated.

Radiotherapy and chemotherapy

In the majority of primary CNS tumours, radiation and chemotherapy are used to control disease and extend survival rather than for cure. Meningioma and pituitary adenoma offer the best chance of life-long remission. The gliomas are incurable; high-grade, WHO grade IV disease still carries a median survival of just over 1 year. In this situation, patient and family should always be involved in decisions regarding treatment. The diagnosis, and often the symptoms, are devastating, and support from palliative care and social work is crucial at an early stage. In WHO grade III disease, prognosis is a little better (2–4 years), and in rarer, more indolent tumours very prolonged survival is possible.

Advances have been made recently in terms of therapeutic outcome. Standard care for WHO grade IV glioblastoma multiforme is now combination radiotherapy with temozolomide chemotherapy; although this improves median survival of the population from only 12 to 14.5 months, up to 25% of patients survive for more than 2 years (compared to approximately 10% with radiotherapy alone). Ten percent will survive more than 5 years with temozolomide (virtually unheard of with radiotherapy alone). Benefits are more likely in well-debulked patients who are younger and fitter. Implantation of chemotherapy gives a small survival benefit.

Understanding of the molecular biology of brain tumours has allowed the use of biomarkers to guide therapy and prognostic discussions.
In patients with methylation of the promoter region of the MGMT (methyl guanine methyl transferase) gene (about 30% of the population) within the tumour, 2-year survival is almost 50%. MGMT reduces the cytotoxicity of temozolomide and this mutation also reduces the enzyme's activity, rendering the tumour more sensitive to chemotherapy. In grade II and III gliomas, the presence of the loss of heterozygosity (LOH) 1p19q chromosomal abnormality confers chemosensitivity and thus improves prognosis. The presence of a rare mutation in the IDH-1 (isocitrate dehydrogenase) gene confers a more favourable prognosis in patients with glioblastoma.

There is a small group of highly malignant grade IV tumours that can be cured with aggressive therapy. Medulloblastomas have a good chance of long-term remission with maximal surgery followed by irradiation of the whole brain and spine; younger patients may also benefit from concomitant and adjuvant chemotherapy. Older patients do not tolerate this, however.

Once tumours relapse, chemotherapy response rates are low and survival is short in high-grade disease. In the more uncommon low-grade tumours, repeated courses of chemotherapy can result in much more prolonged survival.

In metastatic disease, radiotherapy offers a modest improvement in survival but with costs in terms of quality of life; treatment therefore needs careful discussion with the patient. Benefits may be superior in breast cancer but there is little to separate other pathologies. Occasional chemosensitive cancers, such as small-cell lung cancer, may benefit from systemic chemotherapy but intracerebral metastases represent a late stage of disease and have a short prognosis.

Prognosis

The WHO histological grading system is a powerful predictor of prognosis in primary CNS tumours, though it does not yet take account of individual biomarkers. For each tumour type and grade, advancing age and deteriorating functional status are the next most important negative prognostic features. The overall 5-year survival rate of about 14% in adults masks a wide variation that depends on tumour type.

Acoustic neuroma

This is a benign tumour of Schwann cells of the 8th cranial nerve, which may arise in isolation or as part of neurofibromatosis type 2 (see below). When sporadic, acoustic neuroma occurs after the third decade and is more frequent in females. The tumour commonly arises near the nerve's entry point into the medulla or in the internal auditory meatus, usually on the vestibular division. Acoustic neuromas account for 80%–90% of tumours at the cerebellopontine angle.

Clinical features

Acoustic neuroma typically presents with unilateral progressive hearing loss, sometimes with tinnitus. Vertigo is an unusual symptom, as slow growth allows compensatory brainstem mechanisms to develop. In some cases, progressive enlargement leads to distortion of the brainstem and/or cerebellar peduncle, causing ataxia and/or cerebellar signs in the limbs. Distortion of the fourth ventricle and cerebral aqueduct may cause hydrocephalus (see below), which may be the presenting feature. Facial weakness is unusual at presentation but facial palsy may follow surgical removal of the tumour. The tumour may be identified incidentally on cranial imaging.

Investigations

MRI is the investigation of choice (see Fig. 28.40).

Management

Surgery is the treatment of choice. If the tumour can be completely removed, the prognosis is excellent, although deafness is a common complication of surgery. Stereotactic radiosurgery (radiotherapy) may be appropriate for some lesions.

Fig. 28.41 A cafè au lait spot (arrow A) and subcutaneous nodules (arrows B) on the forearm of a patient with neurofibromatosis type 1.

Neurofibromatosis

Neurofibromatosis encompasses two clinically and genetically separate conditions, with an autosomal dominant pattern of inheritance. The more common neurofibromatosis type 1 (NF1) is caused by mutations in the NF1 gene on chromosome 17, half of which are new mutations. NF1 is characterised by neurofibromas (benign peripheral nerve sheath tumours) and skin involvement (Fig. 28.41), and may affect numerous systems (Box 28.76). Neurofibromatosis type 2 (NF2) is caused by mutations of the NF2 gene on chromosome 22 and is characterised by schwannomas (benign peripheral nerve sheath tumours comprising Schwann cells only) with little skin involvement; the clinical manifestations are more restricted to the eye and nervous system (see Box 28.76). Malignant change may occur in NF1 neurofibromas but is rare in NF2 schwannomas. The prevalence of NF1 and NF2 is about 20–50 per 100000 and 1.5 per 100000, respectively.

Von Hippel–Lindau disease

This rare autosomal dominant disease is caused by mutations of the VHL tumour suppressor gene on chromosome 3. It promotes development of tumours affecting the kidney, adrenal gland, CNS, eye, inner ear, epididymis and pancreas, which may undergo malignant change. Benign haemangiomas and haemangioblastomas affect about 80% of patients and are mostly cerebellar and retinal.

Paraneoplastic neurological disease

Paraneoplastic neurological syndromes often present before the underlying tumour declares itself and cause considerable disability. They are discussed in full on page 1165.

Hydrocephalus

Hydrocephalus is the excessive accumulation of CSF within the brain, and may be caused either by increased CSF production, by reduced CSF absorption, or by obstruction of the circulation (Fig. 28.42). Symptoms range from none to sudden death, depending on the speed at which and degree to which hydrocephalus develops. The causes are listed in Box 28.77. The terms “communicating” and “non-communicating” (also known as obstructive) hydrocephalus refer to blockage either outside or within the ventricular system, respectively (Fig. 28.43).

Normal pressure hydrocephalus

Normal pressure hydrocephalus (NPH) is a controversial entity, said to involve intermittent rises in CSF pressure, particularly at night. It is described in old age as being associated with a triad of gait apraxia, dementia and urinary incontinence.

Management

Diversion of the CSF by means of a shunt placed between the ventricular system and the peritoneal cavity or right atrium may result in rapid relief of symptoms in obstructive hydrocephalus. The outcome of shunting in NPH is much less predictable and, until a good response can be predicted, the management of individual cases will remain uncertain.

Idiopathic intracranial hypertension

This usually occurs in young women with high BMI. The annual incidence is about 3 per 100,000. RICP occurs in the absence of a structural lesion, hydrocephalus or other identifiable cause. The aetiology is uncertain but there is an association with obesity in females, perhaps inducing a defect of CSF reabsorption by the arachnoid villi. A number of drugs may be associated, including tetracycline, vitamin A and retinoid derivatives.

Clinical features

The usual presentation is with headache, sometimes accompanied by diplopia and visual disturbance (most commonly, transient obscurations of vision associated with changes in posture). Clinical examination reveals papilloedema but little else. False localising cranial nerve palsies (usually of the 6th nerve) may be present. It is important to record visual fields accurately for future monitoring.

Investigations

Brain imaging is required to exclude a structural or other cause (e.g. cerebral venous sinus thrombosis). The ventricles are typically normal in size or small (“slit” ventricles). The diagnosis may be confirmed by lumbar puncture, which shows raised normal CSF constituents at increased pressure (usually >30 cmH₂O CSF).

Management

Management can be difficult and there is no evidence to support any specific treatment. Weight loss in overweight patients may be helpful if it can be achieved. Acetazolamide or topiramate may help to lower intracranial pressure, the latter perhaps aiding weight loss in some patients. Repeated lumbar puncture is an effective treatment for headache but may be technically difficult in obese individuals and is often poorly tolerated. Patients failing to respond, in whom chronic papilloedema threatens vision, may require optic nerve sheath fenestration or a lumbo-peritoneal shunt.
Head injury

Diagnosis of head trauma is usually clear either from the history or from signs of external trauma to the head. Brain injury is more likely with skull fracture but can occur without. Individual cranial nerves may be damaged in fractures of the facial bones or skull base. Intracranial effects can be substantial and take several forms: extradural haematoma (collection of blood between the skull and dura); subdural haematoma (collection of blood between the dura and the surface of the brain); intracerebral haematoma; or diffuse axonal injury.

Whatever pathology occurs, the resultant RICP may lead to coning (see Figs. 28.36 and 28.37). Haematomas are identified by CT and management is by surgical drainage, usually via a burr hole. Penetrating skull fractures lead to increased infection risk. Long-term sequelae include headache, cognitive decline and depression, all contributing to significant social, work, personality and family difficulties.

Subdural haematoma may occur spontaneously, particularly in patients on anticoagulants, in old age and with alcohol misuse. There may or may not be a history of trauma. Patients present with subacute impairment of brain function, both globally (obtundation and coma) and focally (hemiparesis, seizures). Headache may not be present. The diagnosis should always be considered in those who present with reduced conscious level.

Beyond the immediate consequences of brain injury, there is increasing suspicion of long-term consequences, including dementia, postulated after either moderate (or severe) injuries or even after multiple mild injuries, such as in boxers. If substantiated, this would encourage more effort to go into prevention of repeated brain injury in sporting contexts.

Disorders of cerebellar function

Cerebellar dysfunction can manifest as incoordination of limb function, gait ataxia, speech or eye movements. Acute dysfunction may be caused by alcohol or prescription drugs (especially the sodium channel-blocking antiepileptic drugs phenytoin and carbamazepine).

Inflammatory changes in the cerebellum may cause symptoms in the aftermath of some infections (especially herpes zoster) or as a paraneoplastic phenomenon. The hereditary spinocerebellar ataxias are described on page 1169: they manifest as progressive ataxias in middle and old age, often with other neurological features that aid specific diagnosis.

Disorders of the spine and spinal cord

The spinal cord and spinal roots may be affected by intrinsic disease or by disorders of the surrounding meninges and bones. The clinical presentation of these conditions depends on the anatomical level at which the cord or roots are affected, as well as the nature of the pathological process involved. It is important to recognise when the spinal cord is at risk of compression so that urgent action can be taken.

Cervical spondylosis

Cervical spondylosis is the result of osteoarthritis in the cervical spine. It is characterised by degeneration of the intervertebral discs and osteophyte formation. Such ‘wear and tear’ is extremely common and radiological changes are frequently found in asymptomatic individuals over the age of 50. Spondylosis may be associated with neurological dysfunction. In order of frequency, the C5/6, C6/7 and C4/5 vertebral levels affect C6, C7 and C5 roots, respectively (Fig. 28.44).

Cervical radiculopathy

Acute onset of compression of a nerve root occurs when a disc prolapses laterally. More gradual onset may be due to osteophytic encroachment of the intervertebral foramina.

Clinical features

The patient complains of pain in the neck that may radiate in the distribution of the affected nerve root. The neck is held rigidly and neck movements may exacerbate pain. Paraesthesia and sensory loss may be found in the affected segment and there may be lower motor neuron signs, including weakness, wasting and reflex impairment (Fig. 28.45).

Investigations

Where there is no trauma, imaging should not be carried out for isolated cervical pain. MRI is the investigation of choice in those with radicular symptoms. X-rays offer limited benefit, except in excluding destructive lesions, and electrophysiological studies rarely add to clinical examination with MRI.

Management

Conservative treatment with analgesics and physiotherapy results in resolution of symptoms in the great majority of patients, but a few require surgery in the form of discectomy or radicular decompression.
Cervical myelopathy

Dorsomedial herniation of a disc and the development of transverse bony bars or posterior osteophytes may result in pressure on the spinal cord or the anterior spinal artery, which supplies the anterior two-thirds of the cord (see Fig. 28.44).

Clinical features

The onset is usually insidious and painless but acute deterioration may occur after trauma, especially hyperextension injury. Upper motor neuron signs develop in the limbs, with spasticity of the legs usually appearing before the arms are involved. Sensory loss in the upper limbs is common, producing tingling, numbness and proprioception loss in the hands, with progressive clumsiness. Sensory manifestations in the legs are much less common. Neurological deficit usually progresses gradually and disturbance of micturition is a very late feature.

Investigations

MRI (see Fig. 28.44) (or rarely myelography) will direct surgical intervention. The former provides information on the state of the spinal cord at the level of compression.

Management

Surgical procedures, including laminectomy and anterior disectomy, may arrest progression of disability but neurological improvement is not the rule. The decision as to whether surgery should be undertaken may be difficult. Manual manipulation of the cervical spine is of no proven benefit and may precipitate acute neurological deterioration.

Prognosis

The prognosis of cervical myelopathy is variable. In many patients, the condition stabilises or even improves without intervention. If progression results in sphincter dysfunction or pyramidal signs, surgical decompression should be considered.

Lumbar spondylosis

This term covers degenerative disc disease and osteoarthritic change in the lumbar spine. Pain in the distribution of the lumbar or sacral roots (‘sciatica’) is almost always due to disc protrusion but can be a feature of other rare but important disorders, including spinal tumour, malignant disease in the pelvis and tuberculosis of the vertebral bodies.

Lumbar disc herniation

While acute lumbar disc herniation is often precipitated by trauma (usually lifting heavy weights while the spine is flexed), genetic factors may also be important. The nucleus pulposus may bulge or rupture through the annulus fibrosus, giving rise to pressure on nerve endings in the spinal ligaments, changes in the vertebral joints or pressure on nerve roots.

Pathophysiology

The altered mechanics of the lumbar spine result in loss of lumbar lordosis and there may be spasm of the paraspinal musculature. Root pressure is suggested by limitation of flexion of the hip on the affected side if the straight leg is raised (Lasègue sign). If the third or fourth lumbar root is involved, Lasègue sign may be negative, but pain in the back may be induced by hyperextension of the hip (femoral nerve stretch test). The roots most frequently affected are S1, L5 and L4; the signs of root pressure at these levels are summarised in Figure 28.46.

Clinical features

The onset may be sudden or gradual. Alternatively, repeated episodes of low back pain may precede sciatica by months or years. Constant aching pain is felt in the lumbar region and may radiate to the buttock, thigh, calf and foot. Pain is exacerbated by coughing or straining but may be relieved by lying flat.

Investigations

MRI is the investigation of choice if available, since soft tissues are well imaged. Plain X-rays of the lumbar spine are of little value in the diagnosis of disc disease, although they may demonstrate conditions affecting the vertebral body. CT can provide helpful images of the disc protrusion and/or narrowing of exit foramina.

![Fig. 28.44 Magnetic resonance image showing cervical cord compression (arrow) in cervical spondylosis.](image-url)

![Fig. 28.45 Findings in cervical nerve root compression.](image-url)
Management
Some 90% of patients with sciatica recover following conservative treatment with analgesia and early mobilisation; bed rest does not help recovery. The patient should be instructed in back-strengthening exercises and advised to avoid physical manoeuvres likely to strain the lumbar spine. Injections of local anaesthetic or glucocorticoids may be useful adjunctive treatment if symptoms are due to ligamentous injury or joint dysfunction. Surgery may have to be considered if there is no response to conservative treatment or if progressive neurological deficits develop. Central disc prolapse with bilateral symptoms and signs and disturbance of sphincter function requires urgent surgical decompression.

Lumbar canal stenosis
This occurs with a congenitally narrowed lumbar spinal canal, exacerbated by the degenerative changes that commonly occur with age.

Pathophysiology
The symptoms of spinal stenosis are thought to be due to local vascular compromise secondary to the canal stenosis, rendering the nerve roots ischaemic and intolerant of the increased demand that occurs on exercise.

Clinical features
Patients, who are usually in old age, develop exercise-induced weakness and paraesthesia in the legs (‘spinal claudication’). These symptoms progress with continued exertion, often to the point that the patient can no longer walk, but are quickly relieved by a short period of rest. Physical examination at rest shows preservation of peripheral pulses with absent ankle reflexes. Weakness or sensory loss may only be apparent if the patient is examined immediately after exercise.

Investigations
The investigation of first choice is MRI, but contraindications (body habitus, metallic implants) may make CT or myelography necessary.

Spinal cord compression
Spinal cord compression is one of the more common neurological emergencies encountered in clinical practice and the usual causes are listed in Box 28.78. A space-occupying lesion within the spinal canal may damage nerve tissue either directly by pressure or indirectly by interference with blood supply. Oedema from venous obstruction impairs neuronal function, and ischaemia from arterial obstruction may lead to necrosis of the spinal cord. The early stages of damage are reversible but severely damaged neurons do not recover; hence the importance of early diagnosis and treatment.

Clinical features
The onset of symptoms of spinal cord compression is usually slow (over weeks) but can be acute as a result of trauma or metastases (see Figs. 28.44, 28.47 and 28.48), especially if there is associated arterial occlusion. The symptoms are shown in Box 28.79.

Pain and sensory symptoms occur early, while weakness and sphincter dysfunction are usually late manifestations. The signs vary according to the level of the cord compression and the structures involved. There may be tenderness to percussion over the spine if there is vertebral disease and this may be associated with a local kyphosis. Involvement of the roots at the level of the compression may cause dermatomal sensory impairment and corresponding lower motor signs. Interruption of fibres in the spinal cord causes sensory loss and upper motor neuron signs below the level of the lesion, and there is often disturbance of sphincter function. The distribution of these signs varies with the level of the lesion (Box 28.80).

The Brown–Séquard syndrome (see Fig. 28.18E) results if damage is confined to one side of the cord; the findings are explained by the anatomy of the sensory tracts (see Fig. 28.11). With compressive lesions, there is usually a band of pain at the level of the lesion in the distribution of the nerve roots subject to compression.

Investigations
Patients with a history of acute or subacute spinal cord syndrome should be investigated urgently, as listed in Box 28.81. The investigation of choice is MRI (Fig. 28.47), as it can define the extent of compression and associated soft-tissue abnormality (Fig. 28.48). Plain X-rays may show bony destruction and soft-tissue abnormalities. Routine investigations,

Fig. 28.46 Findings in lumbar nerve root compression.
including chest X-ray, may provide evidence of systemic disease. If myelography is performed, CSF should be taken for analysis; in cases of complete spinal block, this shows a normal cell count with a very elevated protein causing yellow discolouration of the fluid (Froin syndrome). The risk of acute deterioration after myelography in spinal cord compression means that the neurosurgeons should be alerted before it is undertaken. Where a secondary tumour is causing the compression, needle biopsy may be required to establish a tissue diagnosis.

**Management**

Treatment and prognosis depend on the nature of the underlying lesion. Benign tumours should be surgically excised, and a good functional recovery can be expected unless a marked neurological deficit has developed before diagnosis. Extrudal compression due to malignancy is the most common cause of spinal cord compression in developed countries and has a poor prognosis. Useful function can be regained if treatment, such as radiotherapy, is initiated within 24 hours of the onset of severe weakness or sphincter dysfunction; management should involve close cooperation with both oncologists and neurosurgeons (p. 139).

Spinal cord compression due to tuberculosis is common in some areas of the world and may require surgical treatment. This should be followed by appropriate antituberculous chemotherapy for an extended period. Traumatic lesions of the vertebral column require specialised neurosurgical treatment.

**Intrinsic diseases of the spinal cord**

There are many disorders that interfere with spinal cord function due to non-compressive involvement of the spinal cord itself. A list of these disorders is given in **Box 28.82**. The symptoms and signs are generally similar to those that would occur with extrinsic compression (see Boxes 28.79 and 28.80), although a suspended sensory loss (see Fig. 28.18F) can occur only with intrinsic disease such as syringomyelia. Uramic symptoms usually occur earlier in the course of an intrinsic cord disorder than with compressive disorders.

Investigation of intrinsic disease starts with imaging to exclude a compressive lesion. MRI provides most information about structural lesions, such as diastematomyelia, syringomyelia (Fig. 28.49) or intrinsic tumours. Non-specific signal change may be seen in the spinal cord in inflammatory (see Fig. 28.25) or infective conditions and metabolic disorders such as vitamin B$_{12}$ deficiency. Lumbar puncture or blood tests may be required to make a specific diagnosis.

### 28.79 Symptoms of spinal cord compression

- **Pain**
  - Localised over the spine or in a root distribution, which may be aggravated by coughing, sneezing or straining
- **Sensory**
  - Paraesthesia, numbness or cold sensations, especially in the lower limbs, which spread proximally, often to a level on the trunk
- **Motor**
  - Weakness, heaviness or stiffness of the limbs, most commonly the legs
- **Sphincters**
  - Urgency or hesitancy of micturition, leading eventually to urinary retention

### 28.80 Signs of spinal cord compression

**Cervical, above C5**

- Upper motor neuron signs and sensory loss in all four limbs
- Diaphragm weakness (phrenic nerve)

**Cervical, C5–T1**

- Lower motor neuron signs and segmental sensory loss in the arms; upper motor neuron signs in the legs
- Respiratory (intercostal) muscle weakness

**Thoracic cord**

- Spastic paraplegia with a sensory level on the trunk
- Weakness of legs, sacral loss of sensation and extensor plantar responses

**Cauda equina**

- Spinal cord ends approximately at the T12/L1 spinal level and spinal lesions below this level can cause lower motor neuron signs only by affecting the cauda equina

### 28.81 Investigation of acute spinal cord syndrome

- Magnetic resonance imaging of spine or myelography
- Plain X-rays of spine
- Chest X-ray
- Cerebrospinal fluid
- Serum vitamin B$_{12}$
**Diseases of peripheral nerves**

Disorders of the peripheral nervous system are common and may affect the motor, sensory or autonomic components, either in isolation or in combination. The site of pathology may be nerve root (radiculopathy), nerve plexus (plexopathy) or nerve (neuropathy). Neuropathies may present as mononeuropathy (single nerve affected), multiple mononeuropathies (‘mononeuritis multiplex’) or a symmetrical polyneuropathy (Box 28.83). Cranial nerves 3–12 share the same tissue characteristics as peripheral nerves elsewhere and are subject to the same range of diseases.

**Pathophysiology**

Damage may occur to the nerve cell body (axon) or the myelin sheath (Schwann cell), leading to axonal or demyelinating neuropathies. The distinction is important, as only demyelinating neuropathies are usually susceptible to treatment. Making the distinction requires neurophysiology (nerve conduction studies and EMG). Neuropathies can occur in association with many systemic diseases, toxins and drugs (Box 28.84).

**Clinical features**

Motor nerve involvement produces features of a lower motor neuron lesion. Symptoms and signs of sensory nerve involvement depend on the type of sensory nerve involved; small-fibre neuropathies are often painful. Autonomic involvement may cause postural hypotension, disturbances of sweating, cardiac rhythm and gastrointestinal, bladder and sexual functions; isolated autonomic neuropathies are rare and more commonly complicate other neuropathies.

**Investigations**

The investigations required reflect the wide spectrum of causes (Box 28.85). Neurophysiological tests are key in discriminating between demyelinating and axonal neuropathies, and in identifying entrapment neuropathies. Most neuropathies are of the chronic axonal type.

**Entrapment neuropathy**

Focal compression or entrapment is the usual cause of a mononeuropathy. Symptoms and signs of entrapment neuropathies are listed in Box 28.86. Entrapment neuropathies may affect anyone, but diabetes,
Fig. 28.49 Sagittal magnetic resonance image showing descent of cerebellar tonsils and central syrinx. The MRI shows descent of the cerebellar tonsils (top arrow), with a large central cord syrinx extending down from the cervical cord (middle arrow) to the thoracic cord (bottom arrow).

### 28.83 Causes of polyneuropathy

**Genetic**
- Charcot–Marie–Tooth disease (CMT)
- Hereditary neuropathy with liability to pressure palsies (HNPP)
- Hereditary sensory + autonomic neuropathies (HSN, HSAN)
- Familial amyloid polyneuropathy
- Hereditary neuralgic amyotrophy

**Drugs**
- Amiodarone
- Antibiotics (dapsone, isoniazid, metronidazole, ethambutol)
- Antiretrovirals
- Chemotherapy (cisplatin, vincristine, thalidomide)
- Phenytoin

**Toxins**
- Alcohol
- Nitrous oxide (recreational use)
- Rarely: lead, arsenic, mercury, organophosphates, solvents

**Vitamin deficiencies**
- Thiamin
- Pyridoxine
- Vitamin B₁₂
- Vitamin E

**Infections**
- Human immunodeficiency virus
- Brucellosis

**Inflammatory**
- Guillain–Barré syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Vasculitis (polyarteritis nodosa, granulomatosis with polyangitis (also known as Wegener granulomatosis), rheumatoid arthritis, systemic lupus erythematosus)
- Paraneoplastic (antibody-mediated)

**Systemic medical conditions**
- Diabetes
- Renal failure
- Sarcoidosis

**Malignant disease**
- Infiltration

**Others**
- Paraproteinaemias
- Amyloidosis
- Critical illness polyneuropathy/myopathy

---

### 28.84 Common causes of axonal and demyelinating chronic polyneuropathies

**Axonal**
- Diabetes mellitus
- Alcohol
- Uraemia
- Cirrhosis
- Amyloid
- Myxoedema
- Acromegaly
- Paraneoplasia

**Demyelinating**
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Multifocal motor neuropathy
- Paraprotein-associated demyelinating neuropathy
- Charcot–Marie–Tooth disease type I and type X

**Drugs and toxins (see Box 28.83)**
- Deficiency states (see Box 28.83)
- Hereditary factors
- Infection (see Box 28.83)
- Idiopathic factors

---

### 28.85 Investigation of peripheral neuropathy

**Initial tests**
- Glucose (fasting)
- Erythrocyte sedimentation rate
- C-reactive protein
- Full blood count
- Urea and electrolytes
- Liver function tests
- HIV testing

**If initial tests are negative**
- Nerve conduction studies
- Vitamins E and A
- Genetic testing (see Box 28.83)
- Serum protein electrophoresis
- Vitamin B₁₂, folate
- ANA, ANCA, ENA
- Chest X-ray
- Lyme serology
- Serum angiotensin-converting enzyme
- Serum amyloid

(ANCA = antineutrophil cytoplasmic antibody; ANA = antineutrophil antibody; ENA = extractable nuclear antigen)

excess alcohol or toxins, or genetic syndromes may be predisposing causes. Unless axonal loss has occurred, entrapment neuropathies will recover, provided the primary cause is removed, either by avoiding the precipitation of activity or by surgical decompression.

### Multifocal neuropathy

Multifocal neuropathy (mononeuritis multiplex) is characterised by lesions of multiple nerve roots, peripheral nerves or cranial nerves (Box 28.87). Vasculitis is a common cause, either as part of a systemic disease or isolated to the nerves, or it may arise on a background of a polyneuropathy (e.g. diabetes). Multifocal motor neuropathy (MMN) with conduction block is a rare pure motor neuropathy, typically affecting the arms; it is associated with anti-GM1 antibodies in about 50% and responds to intravenous immunoglobulin.

### Polyneuropathy

A polyneuropathy is typically associated with a ‘length-dependent’ pattern, occurring in the longest peripheral nerves first and affecting the distal lower limbs before the upper limbs. Sensory symptoms and signs develop in an ascending “glove and stocking” distribution. In inflammatory demyelinating neuropathies, the pathology may be more patchy, affecting the upper rather than lower limbs.

### Guillain–Barré syndrome

Guillain–Barré syndrome (GBS) is a heterogeneous group of immune-mediated conditions of acute peripheral nerve inflammation, with an

### 28.87 Causes of multifocal mononeuropathy

**Axonal (defined on nerve conduction studies)**
- Vasculitis (systemic or non-systemic)
- Diabetes mellitus
- Sarcoidosis
- Infection (HSV, hepatitis C, Lyme disease, leprosy, diphtheria)

**Focal demyelination with/without conduction block**
- Multifocal motor neuropathy
- Multiple compression neuropathies (usually in association with underlying disease, such as diabetes or alcoholism)
- Multifocal acquired demyelinating sensory and motor neuropathy (MADSAM)
- Hereditary neuropathy with a predisposition to pressure palsy (autosomal dominant, peripheral myelin protein 22 gene)
- Lymphoma

Incidence of 1–2/100,000/year. In Europe and North America, the most common variant is an acute inflammatory demyelinating polyneuropathy (AIDP). Axonal variants, either motor (acute motor axonal neuropathy, AMAN) or sensorimotor, are more common in China and Japan, and account for 10% of GBS in Western countries, often associated with *Campylobacter jejuni*. The hallmark is an acute paralysis evolving over days or weeks, with loss of tendon reflexes. About two-thirds of those with AIDP have a prior history of infection, and an autoimmune response triggered by the preceding infection is thought to cause peripheral nerve inflammation. A number of GBS variants have been described, associated with specific anti-ganglioside antibodies; the best recognised is Miller Fisher syndrome, which involves anti-GQ1b antibodies.

### Clinical features

Distal paraesthesia and pain precede muscle weakness that ascends rapidly from lower to upper limbs and is more marked proximally than distally. Facial and bulbar weakness commonly develops, and respiratory weakness requiring ventilatory support occurs in 20% of cases. Weakness progresses over a maximum of 4 weeks (usually less). Rapid deterioration to respiratory failure can develop within hours. Examination shows diffuse weakness with loss of reflexes. Miller Fisher syndrome presents with internal and external ophthalmoplegia, ataxia and areflexia.

### Investigations

The CSF protein is raised, but may be normal in the first 10 days. There is usually no increase in CSF white cell count (>50×10^6 cells/L suggests an alternative diagnosis, though the cell count may be considerably higher in HIV infection). Electrophysiological changes may emerge after a week or so, with conduction block and multifocal motor slowing, sometimes most evident proximally as delayed F waves. Antibodies to the ganglioside GM1 are found in about 25%, usually the motor axonal form. Other causes of an acute neuromuscular paralysis should be considered (e.g. polymyelitis, botulism, acute intermittent porphyria, diphtheria, spinal cord syndromes or myasthenia), via the history and examination. Nerve roots are an important site of inflammation and contrast uptake is sometimes seen here in contrast-enhanced MRI spinal cord imaging.

### Management

Active treatment with plasma exchange or intravenous immunoglobulin therapy shortens the duration of ventilation and improves prognosis. In severe GBS, both intravenous immunoglobulin (IVIg) and plasma exchange started within 2 weeks of onset hasten recovery, with similar rates of adverse effects but IVIg treatment is significantly more likely to be completed than plasma exchange. The choice of treatment often depends on logistical considerations. Overall, 80% of patients recover completely within 3–6 months, 4% die and the remainder suffer residual neurological disability, which can be severe. Adverse prognostic features include older age, rapid deterioration to ventilation and evidence of axonal loss on EMG. Supportive measures to prevent pressure sores and deep venous thrombosis are essential. Regular monitoring of respiratory function (vital capacity) is needed in the acute phase, as respiratory failure may develop with little warning.

### Chronic polyneuropathy

The most common axonal and demyelinating causes of polyneuropathy are shown in Box 28.84. A chronic symmetrical axonal polyneuropathy, evolving over months or years, is the most common form of chronic neuropathy. Diabetes mellitus is the most common cause but in about 25%–50% no cause can be found.

#### Hereditary neuropathy

Charcot–Marie–Tooth disease (CMT) is an umbrella term for the inherited neuropathies. The members of this group of syndromes have different clinical and genetic features. The most common CMT is the autosomal dominant inherited CMT type 1, usually caused by a duplication in the PMP-22 gene. Common signs are distal wasting (‘inverted champagne bottle’ legs), often with pes cavus, and predominantly motor involvement. X-linked and recessively inherited forms of CMT, causing demyelinating or axonal neuropathies, also occur.
### Chronic demyelinating polyneuropathy

The acquired chronic demyelinating neuropathies include chronic inflammatory demyelinating peripheral neuropathy (CIDP), multifocal motor neuropathy (see above) and paraprotein-associated demyelinating neuropathy. CIDP typically presents with relapsing or progressive motor and sensory changes, evolving over more than 8 weeks (in distinction to the more acute GBS). It is important to recognise, as it usually responds to intravenous immunoglobulin and other immunotherapies such as glucocorticoids or plasma exchange.

Some 10% of patients with acquired demyelinating polyneuropathy have an abnormal serum paraprotein, sometimes associated with a monoclonal gamopathy of uncertain significance (MGUS) or lymphoproliferative malignancy. Those with distal sensory involvement and prominent neuropathic tremor may also demonstrate positive antibodies to myelin-associated glycoprotein (MAG antibodies).

### Brachial plexopathy

Trauma usually damages either the upper or the lower parts of the brachial plexus, according to the mechanics of the injury. The clinical features depend on the anatomical site of the damage (Box 28.88). Lower parts of the brachial plexus are vulnerable to infiltration from breast or apical lung tumours (Pancoast tumour) or damage by therapeutic irradiation. The lower plexus may also be compressed by a cervical rib or fibrous band between C7 and the first rib at the thoracic outlet.

Neuralgic amyotrophy (also known as brachial neuritis) presents as an acute brachial plexopathy of probable inflammatory origin. Severe shoulder pain precedes the appearance of a patchy upper brachial plexus lesion, with motor and/or sensory involvement. There is no specific treatment and recovery is often incomplete; it may recur in about 25% and there is a rare autosomal dominant hereditary form. The appearance of vesicles should indicate the alternative diagnosis of motor zoster.

### Lumbosacral plexopathy

Lumbosacral plexus lesions may be caused by neoplastic infiltration or compression by retroperitoneal haematoma. A small-vessel vasculopathy can produce a unilateral or bilateral lumbar plexopathy in association with diabetes mellitus (“diabetic amyotrophy”) or an idiopathic form in non-diabetic patients. This presents with painful wasting of the quadriceps with weakness of knee extension and an absent knee reflex.

### Spinal root lesions

Spinal root lesions (radiculopathy) are described above. Clinical features include muscle weakness and wasting and dermatomal sensory and reflex loss, which reflect the pattern of the roots involved. Pain in the muscles innervated by the affected roots may be prominent.

### Diseases of the neuromuscular junction

#### Myasthenia gravis

This is the most common cause of acutely evolving, fatigable weakness and preferentially affects ocular, facial and bulbar muscles.

### Pathophysiology

Myasthenia gravis is an autoimmune disease, most commonly (80% of cases) caused by antibodies to acetylcholine receptors in the post-junctional membrane of the neuromuscular junction. The resultant blockage of neuromuscular transmission and complement-mediated inflammatory response reduces the number of acetylcholine receptors and damages the end plate (Fig. 28.50). Other antibodies can produce a similar clinical picture, most notably autoantibodies to muscle-specific kinase (MuSK), which is involved in the regulation and maintenance of acetylcholine receptors.

About 15% of patients (mainly those with late onset) have a thymoma, most of the remainder displaying thymic follicular hyperplasia. Myasthenic patients are more likely to have associated organ-specific autoimmune diseases. Triggers are not always evident but some drugs (e.g. penicillamine) can precipitate an antibody-mediated myasthenic syndrome that may persist after drug withdrawal. Other drugs, especially amino-glycosides and quinolones, may exacerbate the neuromuscular blockade and should be avoided in patients with myasthenia.

### Clinical features

Myasthenia gravis usually presents between the ages of 15 and 50 years and there is a female preponderance in younger patients. In older patients, males are more commonly affected. It tends to run a relapsing and remittent course.

The most evident symptom is fatigable muscle weakness; movement is initially strong but rapidly weakens as muscle use continues. Worsening of symptoms towards the end of the day or following exercise is characteristic. There are no sensory signs or signs of involvement of the CNS, although weakness of the oculomotor muscles may mimic a central eye movement disorder. The first symptoms are usually intermittent ptosis or diplopia but weakness of chewing, swallowing, speaking or limb movement also occurs. Resting of the eyelids (looking downwards) may be followed by increased reflex elevation with up-gaze (so-called Cogan’s lid twitch sign). Any limb muscle may be affected, most commonly those of the shoulder girdle; the patient is unable to undertake tasks above shoulder level, such as combing the hair, without frequent rests. Respiratory muscles may be involved and respiratory failure is an avoidable cause of death. Aspiration may occur if the cough is ineffective. Ventilatory support is required where weakness is severe or of abrupt onset. Subtypes of myasthenia gravis include oculor myasthenia, where disease is limited to eye muscles, and generalised myasthenia, where more widespread muscle involvement is seen which can include bulbar and respiratory muscles. There is often overlap between these subtypes. Congenital (genetic) forms of myasthenia also exist and do not have an autoimmune basis.

### Investigations

Serological investigations play an important role in the diagnosis of myasthenia gravis. Acetylcholine receptor antibodies are highly specific, but seronegative cases also exist and further serological testing, e.g. for MuSK antibodies, should be performed if ACHR antibodies are negative. Anti-MuSK antibodies are associated with prominent bulbar involvement.

Neuropsychological assessment is important in establishing the diagnosis. Repetitive stimulation during nerve conduction studies may show a characteristic decremental response if the muscle has been clinically affected. Specialised single fibre EMG changes such as ‘jitter’ may also be seen. All patients should have a thoracic CT or MRI to exclude...
thymoma, especially those without anti-acetylcholine receptor antibodies. Screening for associated autoimmune disorders, particularly thyroid disease, is important.

Intravenous injection of the short-acting anticholinesterase edrophonium bromide (the Tensilon test) is less widely used than before and requires specialist involvement in cases where there is diagnostic doubt. Structural imaging (e.g. MRI of brainstem) may be needed to exclude alternative diagnoses that can cause ocular-bulbar weakness.

**Management**

The goals of treatment are to maximise the activity of acetylcholine at remaining receptors in the neuromuscular junctions and to limit or abolish the immunological attack on motor end plates.

The duration of action of acetylcholine is prolonged by inhibiting acetylcholinesterase. The most commonly used anticholinesterase drug is pyridostigmine. Muscarinic side-effects, including diarrhoea and colic, may be controlled by propantheline.

Myasthenia gravis can cause life-threatening disease, often referred to as ‘myasthenic crisis’, when bulbar and respiratory failure occurs. Prompt acute immunotherapy, often using intravenous immunoglobulin or plasma exchange is required, together with a longer-term immunosuppressive approach. Supportive respiratory care, and early involvement of intensive care teams, is important during these periods.

Immunological treatment of myasthenia is outlined in Box 28.89. Thymoma should be managed with joint oncology and thoracic surgery input. Prognosis is variable and remissions may occur spontaneously. When myasthenia is entirely ocular, prognosis is excellent and disability slight. Younger seropositive patients with generalised disease may benefit from thymectomy in the absence of thymoma, while older patients are less likely to have a remission despite treatment. Rapid progression of the disease more than 5 years after onset is uncommon.

Some medications, such as aminoglycoside antibiotics, can worsen myasthenia gravis.

**Lambert–Eaton myasthenic syndrome**

Other rarer conditions can present with muscle weakness due to impaired transmission across the neuromuscular junction. The most common of these is the Lambert–Eaton myasthenic syndrome (LEMS), which can occur as an inflammatory or paraneoplastic phenomenon. Antibodies to pre-synaptic voltage-gated calcium channels (see Fig. 28.50) impair transmitter release. Patients may have autonomic dysfunction (e.g. dry mouth) in addition to muscle weakness but the cardinal clinical sign is absence of tendon reflexes, which return after sustained contraction of the relevant muscle. The condition is associated with underlying malignancy in a high percentage of cases and investigation must be directed towards identifying any neoplasm. Diagnosis is made electrophysiologically on the presence of post-tetanic potentiation of motor response to nerve stimulation at a frequency of 20–50/sec. Treatment is with 3,4-diaminopyridine, or pyridostigmine and immunosuppression.

**Diseases of muscle**

Muscle disease, either hereditary or acquired, is rare. Most typically, it presents with a proximal symmetrical weakness. Diagnosis is dependent on recognition of clinical clues, such as cardiorespiratory involvement, evolution, family history, exposure to drugs, the presence of contractures, myotonia and other systemic features, and on investigation findings, most importantly EMG and muscle biopsy. Hereditary syndromes include the muscular dystrophies, muscle channelopathies,
28.89 Immunological treatment of myasthenia

**Acute treatments**

*Intravenous immunoglobulin*
- Lowers production of antibodies and rapidly reduces weakness

**Plasma exchange**
- Removing antibody from the blood may produce marked improvement; this is usually brief, so is normally reserved for myasthenic crisis or for pre-operative preparation

**Long-term treatments**

*Glucocorticoid treatment*
- Improvement can be preceded by marked exacerbation of myasthenic symptoms, so treatment should be initiated cautiously in an environment where deterioration can be managed. In an outpatient setting many neurologists start corticosteroids at a low dose and increase gradually
- Usually necessary to continue for months or years, risking adverse effects

*Pharmacological immunosuppression treatment*
- Azathioprine 2.5 mg/kg daily reduces the necessary dosage of glucocorticoids and may allow withdrawal. Effect on clinical features may be delayed for months
- Mycophenolate mofetil and rituximab are both used, although high-quality evidence is currently lacking
- Thymectomy
  - Likely to be required for thymoma
  - Should be considered in any antibody-positive patient under 45 years with symptoms not confined to extraocular muscles, unless the disease has been established for more than 7 years

Metabolic myopathies (including mitochondrial diseases) and congenital myopathies.

**Muscular dystrophies**

These are inherited disorders with progressive muscle destruction and may be associated with cardiac and/or respiratory involvement and sometimes non-myopathic features (Box 28.90). Myotonic dystrophy is the most common, with a prevalence of about 12/100 000.

**Clinical features**

The pattern of the clinical features is defined by the specific syndromes. Onset is often in childhood, although some patients, especially those with myotonic dystrophy, may present as adults. Wasting and weakness are usually symmetrical, without fasciculation or sensory loss, and tendon reflexes are usually preserved until a late stage. Weakness is usually proximal, except in myotonic dystrophy type 1, when it is distal.

**Investigations**

The diagnosis can be confirmed by specific molecular genetic testing, supplemented with EMG and muscle biopsy if necessary. Creatine kinase is markedly elevated in the dystrophinopathies (Duchenne and Becker) but is normal or moderately elevated in the other dystrophies. Screening for an associated cardiac abnormality (cardiomyopathy or dysrhythmia) is important.

**Management**

There is no specific therapy for most of these conditions but physiotherapy and occupational therapy help patients cope with their...
disability. Glucocorticoids can be used in Duchenne muscular dystrophy but side-effects should be anticipated and avoided by dose modification. Treatment of associated cardiac failure or arrhythmia (with pacemaker insertion if necessary) may be required; similarly, management of respiratory complications (including nocturnal hypoventilation) can improve quality of life. Improvements in non-invasive ventilation have led to significant improvements in survival for patients with Duchenne muscular dystrophy. Genetic counselling is important.

**Inherited metabolic myopathies**

There are a large number of rare inherited disorders that interfere with the biochemical pathways that maintain the energy supply (adenosine triphosphate, ATP) to muscles. These are mostly recessively inherited deficiencies in the enzymes necessary for glycogen or fatty acid (β-oxidation) metabolism (Box 28.91). They typically present with muscle weakness and pain.

**Mitochondrial disorders**

Mitochondrial diseases are discussed on page 47. Mitochondria are present in all tissues and dysfunction causes widespread effects on vision (optic atrophy, retinitis pigmentosa, cataracts), hearing (sensorineural deafness) and the endocrine, cardiovascular, gastrointestinal and renal systems. Any combination of these should raise the suspicion of a mitochondrial disorder, especially if there is evidence of maternal transmission.

Mitochondrial dysfunction can be caused by alterations in either mitochondrial DNA or genes encoding for oxidative processes. Genetic abnormalities or mutations in mitochondrial DNA may affect single individuals and single tissues (most commonly muscle). Thus, patients with exercise intolerance, myalgia and sometimes recurrent myoglobinuria may have isolated pathogenic mutations in genes encoding for oxidation pathways.

Inherited disorders of the oxidative pathways of the respiratory chain in mitochondria cause a group of disorders, either restricted to the muscle or associated with non-myopathic features (Box 28.92). Many of these mitochondrial disorders are inherited via the mitochondrial genome, down the maternal line. Diagnosis is based on clinical appearances, supported by muscle biopsy appearance (usually with ‘ragged red’ and/or cytochrome oxidase-negative fibres), and specific mutations either on blood or, more reliably, muscle testing. Mutations may be due either to point mutations or to deletions of mitochondrial DNA.

A disorder called Leber hereditary optic neuropathy (LHON) is characterised by acute or subacute loss of vision, most frequently in males, due to bilateral optic atrophy. Three point mutations account for more than 90% of LHON cases.

**Channelopathies**

Inherited abnormalities of the sodium, calcium and chloride ion channels in striated muscle produce various syndromes of familial periodic paralysis, myotonia and malignant hyperthermia, which may be recognised by their clinical characteristics and potassium abnormalities (Box 28.93). Genetic testing is available.

**Acquired myopathies**

These include the inflammatory myopathies, or myopathy associated with a range of metabolic and endocrine disorders or drug and toxin exposure (Fig. 28.51).

Multiple Choice Questions

28.1. A patient describes a two-day history of progressive tingling and numbness, starting in both feet but now including both arms. She has difficulty walking today. Examination shows mildly reduced sensation in arms and legs and mild weakness, with reduced reflexes. Where is the most likely location of the lesion?

A. Cerebral hemispheres  
B. Spinal cord  
C. Nerve roots and peripheral nerve  
D. Neuromuscular junction  
E. Muscle

Answer: C.

The symmetrical involvement of both sensory and motor modalities, together with reduced reflexes, is consistent with a peripheral nerve localisation. Evolution of symptoms over this time course suggests an inflammatory cause, such as Guillain-Barré syndrome (GBS). Prompt recognition is important since bulbar and respiratory weakness can develop, and supportive care, including respiratory support, can be required. GBS responds to treatment with intravenous immunoglobulin or plasma exchange. Neuromuscular disease and muscle disease do not cause sensory disturbance, and lesions in the spinal cord or cerebral hemispheres are usually associated with brisk reflexes.

28.2. Which of the following statements about neuroimaging is true?

A. Computed tomography should always be performed before lumbar puncture in suspected meningitis  
B. Computed tomography is the investigation of choice for a thunderclap headache  
C. Accurate imaging of cerebral blood vessels requires invasive angiography  
D. A diagnosis of multiple sclerosis (MS) always requires magnetic resonance (MR) imaging  
E. Parkinson's disease should only be diagnosed following a positive dopamine active transporter (DAT) scan

Answer: B.

Thunderclap headache (a very severe headache of abrupt onset, reaching maximum intensity within 60 seconds) should always raise the possibility of a serious underlying cause and is a medical emergency. An important cause is subarachnoid haemorrhage. Computed tomography is a rapid and widely available imaging modality for detection of acute bleeding. Modern neuroimaging allows blood vessels to be visualised without the need for invasive angiography. MR imaging plays an important role in the diagnosis of MS by helping to demonstrate dissemination of lesions in time and space, and excluding alternative diagnoses; however, MS can also be diagnosed in settings where MR imaging is not available.

28.3. A 65-year-old man from the UK presents with a three-day history of bilateral leg weakness and numbness. Last year he had an episode of left optic neuritis, which did not fully resolve. On examination he is afebrile, with severe bilateral leg weakness (MRC power grade 1/5 throughout) and has brisk lower limb reflexes with a sensory level at T4. Magnetic resonance imaging (MRI) shows an inflammatory lesion in the thoracic spinal cord stretching from T3 to T7. What is the most specific diagnostic investigation to be performed next?

A. Cerebrospinal fluid (CSF) analysis for oligoclonal bands  
B. CSF analysis for schistosomiasis  
C. Blood test for aquaporin-4 antibodies

Answer: D. MRI of the head

E. Whole-body positron emission tomography (PET)

Answer: C.

The clinical syndrome is severe optic nerve and spinal cord inflammation, with imaging evidence of longitudinally extensive transverse myelitis (LETM). While optico-spinal inflammation is most commonly seen in multiple sclerosis (MS), the severe nature of both lesions and the long spinal cord lesion (over 3 vertebral segments in length) are not typical for MS. While infections, including schistosomiasis, can cause long spinal cord lesions, the most likely cause for this clinical picture is neuromyelitis optica spectrum disorder (NMOSD), and aquaporin-4 antibodies are highly specific for this diagnosis. NMOSD can also occur with myelin oligodendrocyte glycoprotein (MOG) antibodies, as well as seronegative cases.

28.4. Which of the following statements about cryptococcal meningitis is true?

A. Only immunosuppressed individuals develop cryptococcal meningitis  
B. Cryptococcal meningitis is a cause of high cerebrospinal fluid protein and glucose  
C. Cerebrospinal fluid India ink test is the investigation of choice for cryptococcal meningitis  
D. High cerebrospinal fluid pressure in cryptococcal meningitis is treated with frequent, often daily, lumbar punctures  
E. Cryptococcal antigen may be present in cerebrospinal fluid, but not in the serum

Answer: D.

Although cryptococcal meningitis (CM) usually occurs in the immunocompetent, it can occur in the immunocompetent. CM results in a high cerebrospinal fluid (CSF) protein and low CSF glucose. Cryptococcal antigen is present in the CSF and sometimes the serum. The India ink test is still used in some regions but sensitivity is limited, particularly in non-HIV-related CM. High CSF pressure in CM is treated with frequent, sometimes daily, lumbar punctures.

28.5. Which of the following statements about seizures is true?

A. All patients who have had a confirmed seizure should be told not to drive  
B. The electroencephalogram (EEG) is always abnormal in people with epilepsy  
C. Neuroimaging should be performed on all individuals who have had a generalized seizure  
D. Neuroimaging is not required for individuals who have had a focal seizure  
E. Anticonvulsants should be started after a first seizure

Answer: A.

It is the physician's prime duty to ensure that the patient is aware of the legal obligation to stop driving and inform the relevant driving authority after having a single seizure. In the UK, patients are usually eligible to drive a motor vehicle six months after a single seizure provided there are no factors that would increase the risk of further seizure. There are far more stringent criteria for heavy goods and public service vehicle drivers. EEG can be normal in people with epilepsy, and neuroimaging is particularly important in individuals who have focal-onset seizures.

Clinical examination in stroke

1. General appearance
   - Conscious level
   - Gaze deviation
   - Facial symmetry

   ▲ Left upper motor neuron pattern of facial weakness

2. Pulse
   - Rate and rhythm

   ▲ Atrial fibrillation

3. Blood pressure, carotid bruits and cardiac auscultation

4. Higher cerebral function
   - Dysphasia or dysarthria
   - Attention and neglect
   - Abbreviated mental test

5. Cranial nerve function
   - Swallow
   - Horner syndrome
   - Internuclear ophthalmoplegia
   - Cranial nerve palsy, e.g. 3rd, 6th, 7th or 12th
   - Visual field loss

   ▲ Visual field defect – left homonymous hemianopia

6. Motor system
   - Tone
   - Strength, including pronator drift
   - Co-ordination
   - Tendon reflexes
   - Plantar reflexes

   ▲ Left pronator drift

7. Sensory system
   - Touch sensation
   - Cortical sensory function: sensory inattention or neglect
   - Joint position sense

   ▲ Extensor plantar reflex

8. Gait
   - Sitting balance
   - Standing balance
   - Ataxic gait pattern
   - Hemiparetic gait pattern
### General examination

#### Skin
- Xanthelasma
- Rash (e.g. vasculitic, splinter haemorrhages)
- Colour change (limb ischaemia, deep vein thrombosis)
- Pressure sores or early pressure injury

#### Eyes
- Diabetic retinopathy
- Hypertensive retinopathy
- Cholesterol emboli
- Papilloedema (unexpected in stroke)
- Subhyaloid haemorrhages (after subarachnoid haemorrhage)

#### Cardiovascular system
- Atrial fibrillation
- Blood pressure (high or low)
- Carotid bruit
- Cardiac murmurs (source of embolism, e.g. endocarditis)
- Peripheral pulses and bruises (generalised arteriopathy)

#### Respiratory system
- Signs of pulmonary oedema or infection
- Oxygen saturation

#### Abdomen
- Palpable bladder (urinary retention)
- Organomegaly

#### Locomotor system
- Injuries sustained during collapse (e.g. hip fracture)
- Comorbidities that influence recovery (e.g. osteoarthritis)

### Rapid clinical assessment of suspected stroke

#### Exclusion of hypoglycaemia
- Bedside blood glucose testing

#### Measure blood pressure
- Significant hypertension may require treatment (e.g. in acute intracerebral haemorrhage, or if thrombolysis is being considered)

#### National Institutes of Health Stroke Scale (NIHSS)
A formalised neurological examination and a measure of stroke severity which can be useful for organising acute stroke assessment, monitoring and communicating stroke severity.

### Score
0 to 2: 0 to 5 mild, 5 to 15 moderate, more than 16 severe

**Tips:** Score what you see, score the first response (not the best response) and don’t coach the patient. Check if the patient can sit up or stand without support.

The NIHSS does not measure well the severity of posterior circulation and non-dominant hemisphere stroke syndromes.
A stroke is a sudden onset focal cerebral dysfunction due to vascular disease of the brain (Fig. 29.1). Stroke is the third most common cause of disability in the world after ischaemic heart disease and congenital disorders. In Europe, most strokes (about 80%) are caused by cerebral ischaemia and fewer are due to haemorrhage, although there are probably a similar number of deaths due to ischaemic and haemorrhagic stroke worldwide. Subarachnoid haemorrhage (SAH) and cerebral venous thrombosis (CVT) are discussed later in this chapter. Vascular dementia is described on page 1246.

### Functional anatomy and physiology

The paired internal carotid and vertebral arteries supply blood to the brain. Each internal carotid artery bifurcates into the anterior and middle cerebral arteries which supply the anterior cerebral (“anterior circulation”). The vertebral arteries join to form the basilar artery (supplying the brainstem, cerebellum and pons) which bifurcates into the posterior cerebral arteries which supply the posterior cerebral (“posterior circulation”) (Fig. 29.2). The function of each brain area is described on page 1122. Communicating arteries connect the anterior with the posterior and the left with the right circulations. These anastomoses form the circle of Willis that – if complete – maintains cerebral circulation even if one carotid or vertebral artery is blocked. In health, autoregulation maintains a constant cerebral blood flow across a wide range of arterial blood pressures to meet the high cerebral metabolic activity. This autoregulatory mechanism can be disrupted after stroke. The venous system is formed by a collection of sinuses over the surface of the brain which drain into the jugular veins (Fig. 29.3).

### Investigations

#### Brain imaging

Brain imaging helps to determine the cause of stroke symptoms. Non-contrast (unenhanced) computed tomography (CT) scanning is rapid, sensitive for intracranial haemorrhage and can show cerebral ischaemia or other diagnoses, but does use ionising radiation. In patients with a clinical diagnosis of an acute stroke, a CT scan that shows no intracerebral haemorrhage makes an ischaemic stroke the likelier diagnosis.

Magnetic resonance imaging (MRI) is more sensitive than CT for changes of cerebral ischaemia and provides very detailed images of brain anatomy, although it takes longer than CT to perform (Fig. 29.4). MRI uses powerful magnets that can interfere with medical devices (such as pacemakers) or metal implants, and can be claustrophobic for patients. Diffusion-weighted MRI adds sensitivity for cerebral ischaemia compared with other MRI sequences.

#### Vascular imaging

Imaging of the carotid artery and of intra- and extracranial vessels can influence practice by demonstrating carotid stenosis which guides decisions about carotid endarterectomy, and by showing major vessel occlusion in acute stroke which guides decisions about thrombectomy.

The first-line imaging techniques for vessels supplying the brain can be ultrasound, CT angiography or MR angiography, depending on availability and expertise. Intra-arterial angiography is used less frequently as a primary investigation, although it is often done during neuro-interventional procedures to confirm findings from non-invasive techniques or guide treatment (Fig. 29.5). Vascular imaging can show also major vessel dissection, changes of cerebral vasculitis, intracranial aneurysms or arteriovenous malformations. Transcranial Doppler sonography is used in some centres to identify intracranial stenosis or occlusion.

#### Blood tests

The choice of blood tests should be guided by the clinical situation. A full blood count, electrolytes and renal function are usually indicated. Blood glucose (usually fasting) can diagnose unrecognised diabetes (or poor diabetes control), lipids (cholesterol fractions and triglycerides) may guide lipid-lowering therapy, and C-reactive protein or erythrocyte sedimentation rate may identify an inflammatory response (for example in giant cell arteritis or endocarditis).

---

**Fig. 29.1** A classification of stroke.
Lumbar puncture

Cerebrospinal fluid can show evidence of subarachnoid haemorrhage, but is not used for most stroke patients.

Cardiac investigations

A 12-lead ECG may show atrial fibrillation (AF), an important stroke risk factor, evidence of prolonged hypertension (left ventricular hypertrophy), or previous myocardial infarction. Prolonged ECG monitoring may reveal short periods of AF (‘paroxysmal’ AF), which leads to anticoagulation for prevention of future ischaemic stroke. Management can change when an echocardiogram shows a right-to-left shunt (e.g. a patent foramen ovale), endocarditis or a cardiac tumour.

Presenting problems

Most strokes develop suddenly within a matter of minutes or hours, and are one of the differential diagnoses of patients with almost any acute focal neurological presentation.

Weakness

In severe stroke, involvement of large areas of the cortex or smaller areas of the deep white matter in the cerebrum or brainstem leads to a hemiparesis (see Fig. 28.17). Other patterns of weakness include: face only (usually an upper motor neuron pattern affecting the lower face only); face and arm; leg only (anterior cerebral artery involvement); hand only (often a clumsiness); or a quadraparesis (with brainstem stroke).

Speech disturbance

Stroke can lead to a number of speech abnormalities. Cortical strokes (usually dominant frontal or parietal lobe) can cause dysphasia, with difficulties understanding speech (a receptive dysphasia) or difficulties producing grammatically correct speech (an expressive dysphasia). Stroke in the cortex, deep white matter, cerebellum or brainstem can lead to altered speech (dysarthria). More rarely, isolated difficulties with reading (alexia) or writing (agraphia) occur, but they are more usually associated with other symptoms (see Box 28.2).

Visual deficit

Occlusion of the ophthalmic artery by thrombus leads to sudden blindness in one eye. If the blindness is transient, this is called ‘transient monocular blindness’ or ‘amaurosis fugax’. These symptoms should lead to a similar search for risk factors and cause as stroke symptoms.

Stroke affecting the occipital lobe or optic tracts or radiation leads to a contralateral hemianopia or, in smaller lesions, a partial field defect (see p. 1145).

Visuo-spatial dysfunction

Damage to the non-dominant cortex often results in contralateral visuo-spatial dysfunction, e.g. sensory or visual neglect and apraxia (inability to perform complex tasks despite normal motor, sensory and cerebellar function). Confusion or dysphasia after stroke are sometimes misdiagnosed as delirium.

Ataxia

Stroke causing damage to the cerebellum and its connections can present with an acute ataxia and there may be associated brainstem features such as diplopia and vertigo. The differential diagnosis includes vestibular disorders.
If acute cortical veins. haemorrhage (Fig. 29.3) or ischaemic stroke (Box 29.1) occur during stroke recovery, or during acute intracerebral haemorrhage or acute cerebral venous thrombosis (particularly of the cortical veins), patients can become comatose if they develop space occupying cerebral oedema, or develop complications of stroke such as pneumonia (see Box 9.31).

**Stroke**

Stroke is a common medical emergency. In the UK about 150 per 100000 people have a stroke each year. It is commoner with increasing age, greater poverty and with vascular risk factors (Box 29.1).

**Pathophysiology**

**Cerebral infarction**

Cerebral infarction is usually due to atherothromboembolism. The source of embolism can be the heart, particularly when there is AF, or the rupture of large artery atherosclerosis and subsequent thromboembolism.

Blood flow, or maintain a reduced blood flow that keeps tissue alive but not active. Cerebral tissue begins to die if there are inadequate collateral vessels, or the vessel is not re-opened by endogenous thrombolysis, thrombolytic medication or thrombectomy. The process of cell death leads to oedema of dying tissue, which can be life-threatening if it expands to increase intracranial pressure. Although reopening blood vessels is of overall benefit, restoration of blood supply can lead to a secondary injury which is most obvious clinically in haemorrhagic transformation of an infarct, which is not infrequent (~3%) after thrombolytic therapy.

If the patient survives the acute stages of infarction, healing begins with inflammation to clear dying tissue, recovery of some neurons and reorganisation of some cerebral function to other brain areas.

#### Intracerebral haemorrhage

The commonest cause of intracerebral haemorrhage is the rupture of small blood vessels. Small vessels can be damaged by hypertension, diabetes, amyloid deposition or genetic causes. Rupture of abnormalities of larger vessels such as arteriovenous or cavernous malformations, and sometimes intracranial aneurysms (which usually presents as SAH) can also lead to intracerebral haemorrhage (Fig. 29.6). Haemorrhage leads to harm by direct pressure of the haematoma which can continue to grow after presentation, mass effect from surrounding oedema, and inflammation due to degrading blood products. Haemorrhage recovers with the resorption of blood products, resolution of oedema, healing of neurons and cerebral reorganisation (Box 29.2)

#### Clinical features

Both acute stroke and transient ischaemic attack (TIA) are characterised by a rapid-onset, focal deficit of brain function. Symptoms can be transient (TIA) or persistent (stroke). The symptoms of a typical stroke progress over minutes, affect an identifiable area of brain and are ‘negative’ (i.e. loss of function) (Box 29.3). If symptoms progress over hours or days, or

---

From carotid arteries, vertebral arteries and aortic arch. Intracranial atheroma can lead to in situ thrombosis. Occlusion of the small perforating lenticulostrate arteries in patients with sporadic or genetic small vessel diseases leads to ‘lacunar’ infarctions. Spontaneous cervical artery dissection is an important mechanism in younger people. Infarction can also be the result of low arterial flow, for example severe hypotension (sometimes intraoperative), vessel inflammation in children or adults with vasculitis, or failure in energy production in mitochondrial disease.

After the occlusion of a cerebral artery, the supply of oxygen, glucose and other nutrients to tissue fails, and neuronal functions begin to fail. If there are adequate collateral vessels, these may dilate and restore normal

If significant ‘positive’ features are present (e.g. spreading paraesthesiae, abnormal movements), other diagnoses are more likely (Box 29.3). Persistent or transient symptoms that cannot be localised to one brain area, e.g. syncope, amnesia, delirium and dizziness, are more likely to have causes other than TIA or stroke (see Fig. 9.4 and Box 29.4). It is important to remember that anxiety is common in people presenting with stroke or TIA, but also that people with functional neurological disorders can present with acute onset weakness or collapse (see Chapter 29).

The clinical syndrome of an ischaemic stroke depends on the arterial territory involved and the size of the lesion (see Fig. 29.1). These will both have a bearing on management, such as suitability for carotid endarterectomy. The presence of a unilateral motor deficit, a higher cerebral function deficit such as aphasia or neglect, or a visual field defect usually places the lesion in the cerebral hemisphere. Ataxia, diplopia, vertigo or bilateral weakness usually indicates a lesion in the brainstem or cerebellum. Different combinations of these deficits define several ischaemic stroke syndromes (Fig. 29.7), which reflect the site and size of the lesion and may provide clues to the underlying arterial occlusion.

Reduced conscious level usually indicates a large-volume lesion in the cerebral hemisphere but may result from a lesion in the brainstem or complications such as obstructive hydrocephalus, hypoxia or severe systemic infection (usually pneumonia). The combination of severe headache and vomiting at the onset of the focal deficit is suggestive of intracerebral haemorrhage, although headache is also a feature of giant cell arteritis and arterial dissection.

The definitions of strokes and TIA, are:

- **Transient ischaemic attack (TIA):** a transient focal neurological dysfunction caused by brain or retinal ischaemia with no evidence of infarction, where symptoms resolve within 24 hours.
- **Cerebral ischaemic stroke:** acute focal neurological dysfunction caused by focal infarction at single or multiple sites of brain or retina, with evidence of infarction either from neuroimaging or symptom duration longer than 24 hours.
- **Intracerebral haemorrhage:** acute focal neurological disturbance caused by haemorrhage within the brain parenchyma or ventricular system.

### Investigations

Investigation of suspected stroke aims to confirm the vascular nature of a lesion, distinguish infarction from haemorrhage and identify the underlying vascular disease and risk factors (Boxes 29.5 and 29.6).
**Clinical syndrome** | **Common symptoms** | **Common cause** | **CT scan features**
--- | --- | --- | ---
Total anterior circulation syndrome (TACS) | Combination of:
- Hemiparesis
- Higher cerebral dysfunction (e.g. aphasia)
- Hemisensory loss
- Homonymous hemianopia (damage to optic radiations) | Middle cerebral artery occlusion
Emboli from heart or major vessels | ![CT scan]

Partial anterior circulation syndrome (PACS) | Isolated motor loss (e.g. leg only, arm only, face)
Isolated higher cerebral dysfunction (e.g. aphasia, neglect)
Mixture of higher cerebral dysfunction and motor loss (e.g. aphasia with right hemiparesis) | Occlusion of a branch of the middle cerebral artery or anterior cerebral artery
Emboli from heart or major vessels | ![CT scan]

Lacunar syndrome (LACS) | Pure motor stroke – affects two limbs
Pure sensory stroke
Sensory-motor stroke
No higher cerebral dysfunction or hemianopia | Thrombotic occlusion of small perforating arteries
Thrombosis in situ | ![CT scan]

Posterior circulation stroke (POCS) (lateral view) | Homonymous hemianopia (damage to visual cortex)
Cerebellar syndrome
Cranial nerve syndromes | Occlusion in vertebral, basilar or posterior cerebral artery territory
Cardiac embolism or thrombosis in situ | ![CT scan]

**Fig. 29.7 Clinical and radiological features of the stroke syndromes.** The top three diagrams show coronal sections of the brain and the bottom one shows a sagittal section. The anatomical locations of cerebral functions are shown with the nerve tracts in green. A motor (or sensory) deficit (shown by the areas shaded red) can occur with damage to the relevant cortex (PACS), nerve tracts (LACS) or both (TACS). The corresponding CT scans show horizontal slices at the level of the lesion, highlighted by the arrows.

---

**Neuroimaging**

CT is the most widely available method of imaging the brain. It has reasonable sensitivity for some non-stroke lesions, such as subdural haematomas, subarachnoid haemorrhage and brain tumours, but not others, such as the changes of early multiple sclerosis. CT has a high sensitivity for acute intracranial haemorrhage (see Fig. 29.6). However, soon after symptom onset, CT changes in cerebral infarction may be absent, or very subtle. Signs of infarction develop over time but small cerebral infarcts may never show up on CT imaging. Immediate brain imaging is a help and sometimes essential (see Box 29.7).

Perfusion of brain tissue can be demonstrated with CT after injection of contrast media (i.e. CT perfusion scanning). After ischaemic stroke, this technique can identify areas of brain with low perfusion that might be reversed with thrombolysis or thrombectomy.

MRI scanning times are longer than CT, but MRI diffusion weighted imaging (DWI) can detect ischaemia earlier than CT. It may not show changes in up to a third of stroke patients (see Fig. 29.4). MRI is more sensitive than CT in detecting strokes affecting the brainstem and cerebellum, and, unlike CT, can reliably distinguish haemorrhagic from ischaemic stroke weeks after the onset. CT and MRI may reveal clues as to the nature of the arterial lesion. For example, there may be a small, deep lacunar infarct indicating small-vessel disease, or a more peripheral infarct suggesting other causes (see Fig. 29.7). The location of an intracerebral haemorrhage might indicate the presence of an underlying vascular malformation, aneurysm or amyloid angiopathy.

A ‘positive scan’ is not needed to make a diagnosis of acute ischaemic stroke. A typical stroke syndrome with a normal CT (or a CT with no acute changes of stroke) means that an ischaemic stroke is the likeliest diagnosis. This means clinical skills are very important in stroke diagnosis.
Vascular imaging

It is important to identify carotid stenosis in patients with recent ischaemic stroke or TIA. The presence or absence of a carotid bruit is not a reliable indicator of the degree of carotid stenosis. Carotid stenosis can be non-invasively identified with duplex ultrasound, magnetic resonance or computed tomography angiography (MRA or CTA) (see Fig. 29.5), or very occasionally with intra-arterial contrast radiography. Although many patients have intracranial, vertebral artery or aortic arch atherosclerosis, at the time of writing there are no evidenced-based interventions for these lesions. In patients with spontaneous intracerebral haemorrhage, imaging (MRA, CTA or CT venography (CTV)) may identify an underlying macrovascular cause, e.g. intracranial aneurysm, arteriovenous malformation (AVM), or venous sinus thrombosis (see Fig. 29.5). CTA is an important technique to demonstrate large artery occlusion to identify patients who are suitable for thrombectomy.

Cardiac investigations

Approximately 20% of ischaemic strokes are due to embolism from the heart. The most common cause is atrial fibrillation, but prosthetic heart valves, endocarditis, other valve abnormalities and recent myocardial infarction may also lead to cardiogenic embolism.

Atrial fibrillation can be identified on a 12-lead ECG, or more prolonged ECG recording with devices that can record between a few days and many months. A transthoracic or transoesophageal echocardiogram in selected stroke patients can identify endocarditis, atrial myxoma, intracardiac thrombus or patent foramen ovale (PFO). A PFO is a right-to-left cardiac shunt that is usually asymptomatic but can act as a conduit for thrombi from the venous system.

Blood tests

Blood tests can identify high fasting glucose levels, anaemia, electrolyte disturbances or evidence of an inflammatory response (e.g. in temporal arteritis or vasculitis). Clotting abnormalities are a rare cause of ischaemic or haemorrhagic stroke, and tests for thrombophilia or haemophilia without other clinical pointers rarely lead to a change in management. However, in selected patients (for example those with both venous and arterial events) tests for inherited thrombophilia or anti-phospholipid antibodies may be helpful. Intracranial haemorrhage is frequently due to prescribed anticoagulants (direct oral anticoagulants or coumarins like warfarin) and monitoring may be important when reversing the effect of these agents.
disability amongst survivors. For every 1000 patients managed in a stroke unit, an extra 50 will avoid death or long-term disability, compared to those managed in non-specialist wards. Rehabilitation should begin at the same time as acute medical management. Dysphagia is common and can be detected by an early bedside test of swallowing. This allows hydration, feeding and medication to be given safely, if necessary by nasogastric tube. In the acute phase, a checklist may be useful (Box 29.8) to ensure that all the factors that might influence outcome have been addressed.

Neurological deficits may worsen during the first few hours or days after their onset. This may be due to further infarction, haemorrhagic transformation of infarction (most commonly after thrombolysis), or the development of oedema with consequent mass effect. It is important to distinguish these patients from those who are deteriorating as a result of complications such as hypoxia, sepsis, epileptic seizures or metabolic abnormalities that may be reversed more easily. Patients with cerebellar haematomas or infarcts with mass effect may develop obstructive hydrocephalus and some will benefit from insertion of a ventricular drain or decompressive surgery. Some patients with large haematomas or infarction with massive oedema in the cerebral hemispheres may benefit from anti-oedema agents, such as mannitol, or artificial ventilation. Surgical decompression with hemicraniectomy to reduce intracranial pressure should be considered in patients where survival with severe disability is acceptable and surgery is possible within 48 hours.

**Antiplatelet agents**

In the absence of contraindications, aspirin (300 mg daily) should be started immediately after a major ischaemic stroke unless thrombolysis has been given, in which case it should be withheld for at least 24 hours. Aspirin reduces the risk of early ischaemic stroke recurrence and has a small but clinically worthwhile effect on disability (see Fig. 29.8 and Fig. 29.12); it may be given by rectal suppository or by nasogastric tube in dysphagic patients. In minor ischaemic stroke or TIA, two antiplatelet agents (for example clopidogrel and aspirin) for a few weeks reduce the risk of early recurrent stroke.

Considerations specific to use of anticoagulants in old age are given in Box 29.9.

**Coagulation abnormalities**

In patients with intracerebral haemorrhage, coagulation abnormalities should be reversed as quickly as possible to reduce haematoma expansion. This is a problem in patients taking anticoagulant therapy. There is no evidence that clotting factors are useful in the absence of a clotting defect.

**Blood pressure**

Early reduction of blood pressure (<180 mmHg) reduces haematoma expansion and may improve the overall outcome in patients with acute intracerebral haemorrhage. Blood pressure lowering in acute ischaemic stroke does not improve later disability, but reduces intracranial haemorrhage after thrombolysis.

However, reducing blood pressure is very important in the longer term to reduce the risk of recurrent stroke.

**Management of risk factors**

The approaches used are summarised in Fig. 29.12. The average risk of a further stroke is 5%–10% within the first week of an ischaemic stroke or TIA, 15% over the first year (including the early period) and 5% per year thereafter. Patients with ischaemic stroke or TIA should be offered long-term antiplatelet drugs and statins to lower low density lipoprotein cholesterol (LDL-C). For patients in atrial fibrillation, the risk can be reduced substantially with oral anticoagulation with direct oral anticoagulants or warfarin (in selected patients, see Box 29.9). The risk of recurrence after
both ischaemic and haemorrhagic strokes can be reduced by blood pressure reduction, even for those with relatively ‘normal’ blood pressures. Patients should stop smoking. The evidence for change in diet or increasing exercise is weaker, but it is probable these interventions reduce recurrent stroke.

**Fig. 29.9** Complications of acute stroke.

---

### Carotid endarterectomy and arterial angioplasty

Some patients with a carotid territory ischaemic stroke or TIA have >50% stenosis of the carotid artery on the side of the brain lesion. These patients have a greater than average risk of stroke recurrence. For those without major residual disability, removal of the stenosis by carotid endarterectomy reduces the risk of recurrent stroke although the operation itself carries about a 3%–4% stroke risk, depending on the surgical centre. Surgery is most effective in patients with more severe stenoses (70%–99%) and when it is performed within the first couple of weeks after the TIA or ischaemic stroke. Carotid angioplasty and stenting are technically feasible but have not been shown to be as effective as endarterectomy for the majority of eligible patients. Endarterectomy of asymptomatic carotid stenosis reduces stroke risk, but it has a smaller absolute benefit. Whilst stenting of other arteries (vertebral or intracranial) could reduce stroke incidence, at present there is no evidence to support their use in clinical practice.

---

### Rehabilitation

Stroke survivors are often disabled by reduced mobility or upper limb weakness, impaired communication, cognitive impairment, dyspraxia, poor coordination, or visual impairment. Around a third of patients develop dementia after stroke. A minority have persistent dysphagia and some need long-term enteral feeding with a gastrostomy tube. Other long-term stroke complications include neuropathic pain (particularly common after thalamic stroke), limb spasticity, shoulder pain, epilepsy, incontinence, fatigue and anxiety or depression.

The purpose of rehabilitation is to maximise functional recovery and prevent complications. The speed and degree of recovery varies between individuals. Severe strokes (total anterior circulation syndrome or NIHSS score >15) are more likely to cause severe disability and loss of independent living. Other predictors of poor recovery are older age, pre-existing disability, multi-morbidity and pre-existing cognitive impairment.

The goals set during rehabilitation should be achievable, and reached by discussion between the patient and a multidisciplinary team on a dedicated stroke unit, including doctors, nurses, physiotherapists, speech and language therapists, occupational therapists, psychologists and dieticians. Supportive family and social networks are important.
There are three main phases of recovery. Early recovery (first few days) is due to resolution of cerebral oedema and cerebral reperfusion. The second phase – ‘neuroplasticity’ – is when new areas of brain take over from damaged areas of brain. This ‘rewiring’ can occur for a year or even later after stroke but most happens within the first few months. Intensive rehabilitation should begin as early as possible after the first 24 hours, because very early mobilisation (<24 hr) may be harmful. Repetitive practice of lost skills has been shown to increase neuroplasticity. The third phase is adaptive recovery. In this period the patient may learn new strategies to live with their disability and provision can be made for mobility aids, communication aids, or adaptations to the home. Intense therapy in the longer term may be beneficial to some patients and is an area of active research.

It is important not to underestimate the long-term emotional and financial impacts of stroke. Many stroke survivors face an initial loss of identity, loss of income and relationship strain. It is common for stroke survivors to feel fear, anxiety, frustration, anger, sadness and a sense of grief over physical and mental losses. Stroke survivors hoping to return to education or work need specialist vocational support.

Barriers to effective rehabilitation include physical illness; post-stroke pneumonia or delirium, which can delay rehabilitation sessions; pre-existing cognitive impairment or physical frailty; poor motivation and apathy (common in non-dominant hemisphere strokes); fatigue; depression; or pain. When improvements in lost function slow down the focus of therapy shifts to adaptive recovery. Milestones can be used to discuss rehabilitation goals with patients and their carers and to set out realistic expectations for recovery. Physical milestones include sitting balance (e.g. 1 minute unsupported sit), followed by standing balance (e.g. 1 minute), followed by stepping (e.g. 10 steps on the spot) and then walking (e.g. 10 metres).

29.8 How to manage a patient with acute stroke

Airway
- Perform bedside swallowing screen and consider nasogastric tube for feeding if swallowing is unsafe

Breathing
- Check respiratory rate

Circulation
- Check peripheral perfusion, pulse and blood pressure

Hydration
- If signs of dehydration, give fluids parenterally or by nasogastric tube

Nutrition
- Assess nutritional status and provide supplements if needed
- If unable to swallow, consider feeding via nasogastric tube

Medication
- If dysphagic, consider other routes for essential medications

Blood pressure
- Haemorrhagic stroke: consider lowering systolic blood pressure to 130–140 mmHg and maintain this blood pressure for at least 7 days
- Ischaemic stroke: unless there is heart or renal failure, evidence of hypertensive encephalopathy or aortic dissection, do not lower blood pressure abruptly
- Check blood glucose and treat if diabetes is diagnosed
- Avoid hypoglycaemia

Temperature
- If pyrexial, investigate and treat underlying cause
- Control temperature with antipyretics

Pressure areas
- Reduce risk of skin breakdown:
  - Treat infection
  - Maintain nutrition
- Provide pressure-relieving mattress
- Turn immobile patients regularly

Incontinence
- Check for constipation and urinary retention; treat these appropriately
- Avoid urinary catheterisation unless patient is in acute urinary retention or incontinence is threatening pressure areas

Prevention of deep vein thrombosis
- Consider intermittent pneumatic compression stockings in immobile patients

Mobilisation
- Avoid bed rest after the first 24 hours

Research in technologies to assist stroke rehabilitation is ongoing, including transcranial direct current stimulation and vagal stimulators for motor recovery and minor therapy for limb pain and visuospatial neglect.

Causes of ischaemic stroke

Large artery atherosclerosis, small vessel disease and cardioembolism from AF are the commonest causes of ischaemic stroke. Carotid or vertebral artery dissection occasionally leads to stroke. The presenting history often includes minor injury and face or neck pain. After confirmation on angiography (MRA or CTA), treatment is with either antipatelet drugs or anticoagulation, (the latter are more effective). The cause of dissection is unknown in most cases, but collagen disorders, e.g. Ehlers–Danlos syndrome (type 4), are occasionally responsible.

Giant cell arteritis, a vasculitis of large and medium-sized blood vessels, may present with transient monocular blindness, usually with head tenderness, shoulder pain or jaw claudication on chewing. It is important to identify because blindness can be prevented with steroids. Other large artery vasculitis can very rarely present with stroke.

Causes of intracerebral haemorrhage

Most intracerebral haemorrhages result from disease of the small cerebral blood vessels, either due to sporadic small vessel disease or amyloid angiopathy. Anticoagulants, given for AF or metal prosthetic heart valves, increase the risk of intracerebral haemorrhage but almost always to a smaller degree than their reduction in the risk of ischaemic stroke.

Arteriovenous or cavernous malformations (‘cavernomas’) are more commonly discovered after intracerebral haemorrhage in younger people. To reduce the risk of further haemorrhage, it is possible to treat some of these malformations with surgery or radio-surgery. Arteriovenous malformation can be treated by surgical removal, by ligation of the blood vessels that feed or drain the lesion, or most often by radiological injection of material to occlude the fistula or draining veins. However, treatment of these malformations when they are asymptomatic probably leads to more harm than benefit.

Subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH) (see Fig. 29.1) affects about 6 per 100 000 of the population per year. SAH is more common in women, in older people and in those with a family history, or vascular risk factors (particularly smoking and hypertension). About 30% of patients with an aneurysmal SAH die within a month of their bleed; untreated survivors have a recurrence (or rebleed) rate of about 40% in the first 4 weeks.

Most (85%) SAHs are due to saccular or ‘berry’ aneurysms at bifurcations of cerebral arteries (see Fig. 29.2), particularly in the circle of Willis. The most common sites are in the anterior communicating artery (30%), posterior communicating artery (25%) and middle cerebral artery (20%). There is an increased risk in first-degree relatives of those with saccular aneurysms, in patients with polycystic kidney disease and congenital connective tissue disorders such as Ehlers–Danlos syndrome. A minority of SAHs are not associated with aneurysms – the clinical syndrome of ‘peri-mesencephalic haemorrhage’, which have a characteristic appearance on CT and a benign prognosis. Small cortical surface SAH is thought to be due to amyloid angiopathy. Around 5% of SAHs are due to arteriovenous malformations or vertebral artery dissection.

Clinical features

SAH usually presents with a sudden, severe, ‘thunderclap’ headache, which is usually persistent, often accompanied by vomiting, raised blood pressure and neck stiffness or pain. It can occur spontaneously, on physical exertion, straining or during sex. There may be loss of consciousness so SAH should be considered if a patient is found comatose. About 1 patient in 8 with a sudden severe headache has SAH and, in view of this, all who present in this way require investigation to exclude it (Fig. 29.13).

On examination, the patient may be distressed, in pain, with photophobia. There may be neck stiffness due to subarachnoid blood, but this may take some hours to develop. Focal hemisphere signs, such as hemiparesis or aphasia, may be present at onset if there is an associated intracerebral haematoma. A third nerve palsy may be present due to local pressure from an aneurysm of the posterior communicating artery, and patients presenting with a painful third nerve palsy should be investigated urgently for the presence of an expanding aneurysm. Fundoscopy may reveal a subhyaloid haemorrhage, which represents blood tracking along the subarachnoid space around the optic nerve.
Subarachnoid haemorrhage

Fig. 29.12 Strategies for secondary prevention of stroke. 1Lower blood pressure with caution in patients with postural hypotension, renal impairment or severe bilateral carotid stenosis. 2Other statins can be used as an alternative to simvastatin in patients on warfarin or digoxin. 3Warfarin and aspirin have been used in combination in patients with prosthetic heart valves. 4The combination of aspirin and clopidogrel is indicated short term (<21 days) in patients with high-risk TIA (ABC2D score > 4) or mild stroke (NIHSS <3) and low bleeding risk. Afterwards these patients should continue either aspirin or clopidogrel long term. (ACE = angiotensin-converting enzyme; AF = atrial fibrillation; BP = blood pressure; CT = computed tomography; ECG = electrocardiogram; INR = International Normalised Ratio; MRI = magnetic resonance imaging; TIA = transient ischaemic attack; U&Es = urea and electrolytes)

Fig. 29.13 Investigation of subarachnoid haemorrhage. (CSF = cerebrospinal fluid; CT = computed tomography)

29.9 Anticoagulation in old age

- Randomised trials of anticoagulation versus aspirin in older people with atrial fibrillation demonstrate a halving of the risk of stroke from about 4% to about 2% per year. Any increased risk of bleeding is much smaller.
- AF and increased risk of stroke: older age and previous stroke increase the risk of stroke in the presence of atrial fibrillation, and bleeding risk with anticoagulation.
- Falls risk: older patients are more prone to falls, including head injuries, which may increase bleeding risk.

Investigations

The diagnosis of SAH can usually be made by a timely CT read by an expert radiologist but a negative result does not completely exclude it, since small amounts of blood in the subarachnoid space may not be detected by CT, especially if the presentation is delayed by more than a day (see Fig. 29.13). Lumbar puncture should be performed 12 hours after symptom onset if possible, to allow detection of xanthochromia. If either of these tests is positive, CT or digital subtraction cerebral angiography (see Fig. 29.5) is needed to identify an aneurysm.
Management

Nimodipine is given to prevent delayed cerebral ischaemia in the acute phase. Insertion of platinum coils into an aneurysm (via an endovascular procedure) or surgical clipping of the aneurysm neck reduces the risk of both early and late recurrent SAH. Coiling is associated with fewer perioperative complications and better outcomes than surgical clipping: where feasible, it is now the procedure of first choice. Treatment may also be needed for complications of SAH, which include obstructive hydrocephalus (that may require drainage via a shunt), delayed cerebral ischaemia due to vasospasm (which may be treated with vasodilators), hyponatraemia (best managed by fluid restriction) and systemic complications associated with immobility, such as chest infection and venous thrombosis.

Rehabilitation

The pattern of recovery after subarachnoid haemorrhage is different to ischaemic or haemorrhagic stroke, perhaps due to a more widespread brain injury. Even those who make a good physical recovery from a mild SAH often have problems with headache, thinking, fatigue and change in personality. Physical disabilities due to hemiparesis, arm or leg weakness or incoordination may relate to ischaemic or haemorrhagic lesions following aneurysm rupture.

Cerebral venous disease

Thrombosis of the cerebral veins and venous sinuses (cerebral venous thrombosis) is much less common than arterial thrombosis. The main causes are listed in Box 29.10. It may be idiopathic, associated with pregnancy, infection of the cranial sinuses, severe dehydration, or due to other acquired or inherited thrombophilias.

Clinical features

Cerebral venous sinus thrombosis usually presents with symptoms of raised intracranial pressure, seizures and focal neurological symptoms. The clinical features vary according to the sinus involved (Box 29.11 and see Fig. 29.3). Cortical vein thrombosis presents with focal cortical deficits such as aphasia and hemiparesis (depending on the area affected), and epilepsy (focal or generalised). Occlusion of the larger veins may present with severe illness, but also with a milder illness of headache and papilloedema.

Investigations and management

MR venography demonstrates a filling defect in the affected vessel. Anticoagulation, initially with heparin followed by warfarin, is beneficial, even in the presence of venous haemorrhage. In selected patients, endovascular thrombolysis has been advocated. Management of underlying causes and complications, such as persistently raised intracranial pressure, is important.

Multiple Choice Questions

29.1. A 75-year-old woman presents with a transient episode of right facial weakness, right hand weakness and dysarthria, witnessed by her daughter. At her clinic appointment she has a blood pressure of 175/95mmHg. Which area of the brain is likely to have been involved in her symptoms?

A. Right parietal lobe  
B. Left occipital lobe  
C. Brainstem  
D. Left frontal lobe  
E. All of the above

Answer: D.

The right face and hand weakness makes involvement of the contralateral motor cortex, in the precentral gyrus of frontal lobe, most likely.

29.2. In the same patient, stenosis of a cervical artery is found on a CT angiogram of her neck vessels. Which stenosis or stenoses would be an indication for surgical intervention?

A. Left internal carotid stenosis  
B. Right carotid stenosis  
C. Left vertebral artery stenosis  
D. Left subclavian stenosis  
E. Left external carotid stenosis

Answer: A.

Left internal carotid stenosis: stenoses of the other arteries indicates large vessel atheroma, but none would be expected to lead to a left hemisphere transient ischaemic attack.

29.3. For the same patient, a left carotid endarterectomy is planned. Which of the following treatments should be considered (choose all that apply)?

A. Carotid endarterectomy only  
B. Blood pressure lowering  
C. LDL cholesterol lowering  
D. Antiplatelet agent  
E. Anticoagulant

Answer: B, C, D.

Blood pressure lowering, LDL cholesterol lowering and an antiplatelet are all indicated here in addition to carotid endarterectomy. An anticoagulant is only indicated if atrial fibrillation is identified.

29.4. A 54-year-old man has a sudden onset of a severe left hemiparesis and left facial weakness. He has no pain. He is inattentive to his left side. He has atrial fibrillation. He arrives at the Emergency Department 1 hour after the onset of the symptoms. Which are the best differential diagnoses (choose all that apply)?

A. Ischaemic stroke  
B. Intracerebral haemorrhage  
C. Subarachnoid haemorrhage  
D. Transient ischaemic attack  
E. Brain tumour

Answer: A, B.

This man has presented with an acute focal neurological deficit that is severe at 3 hours. This is unlikely to be due to a TIA, and a subarachnoid haemorrhage usually presents with headache or, when severe, coma. Rarely a bleed from a ruptured aneurysm can be predominantly parenchymal with little subarachnoid blood. The sudden onset of symptoms makes a brain tumour unlikely. Both an intracerebral haemorrhage and an ischaemic stroke present with a stroke syndrome.

29.5. In the same patient, a CT of the brain is performed within 30 minutes of his arrival to the Emergency Department, and this CT head is normal at first review. Which of the following statements best describes the situation?

A. An ischaemic stroke is the likeliest diagnosis and thrombolysis is appropriate  
B. An ischaemic stroke is the likeliest diagnosis and thrombolysis is not appropriate  
C. Multiple sclerosis is the likeliest diagnosis and steroids are most appropriate  
D. Immediate thrombectomy is the next best step  
E. Intravenous heparin is appropriate

Answer: A.

A normal CT scan does not preclude a diagnosis of ischaemic stroke, which is the most likely diagnosis here. Because this is the case, thrombolysis is the most important action; thrombectomy is also likely to be indicated, but would need the identification of an occluded artery with an angiogram. A sudden onset of severe cortical symptoms is not a common presentation of multiple sclerosis. Intravenous heparins do not improve recovery in acute ischaemic stroke, even with atrial fibrillation.

The ability to see is an important aspect of everyday life. Although rarely a cause of mortality, visual impairment can have a profoundly negative impact on socioeconomic status.

Globally, although refractive errors and cataract remain the main causes of visual impairment, significant progress has occurred in prevention and treatment. Public health measures have reduced diseases of poor hygiene and unclean water, such as trachoma and onchocerciasis, and greater access to surgery has reduced the burden of untreated cataract and glaucoma. However, conditions associated with longevity, such as age-related macular degeneration, diabetic retinopathy and retinal vein occlusion, are increasing.

Traditionally, ophthalmology relied on other specialties to undertake extraocular investigation and treatment. Medical ophthalmology bypasses that co-dependence, allowing patients with visual disorders to receive overarching care within ophthalmology. As such, it requires a good grounding in medicine and many of its sub-specialties. Medical ophthalmology presents a challenge for a medical textbook as it overlaps with almost all other specialties, but particularly neurology. In this book neuro-ophthalmology is mainly covered in Chapter 28. This chapter concentrates on intraocular inflammation, which was the prime drive to create the specialty, and conditions that require intravitreal injection therapy. It does not therefore represent the totality of the medical ophthalmologist’s workload.

Ophthalmological conditions that are usually managed within non-ophthalmological specialties are discussed in the corresponding chapters, although for ease of reference the more common ophthalmic features of non-ophthalmological conditions are listed throughout this chapter (haematological disease in Box 30.1, diabetes and endocrine disease in Box 30.2, cardiovascular disease in Box 30.3, respiratory disease in Box 30.4, rheumatological/musculoskeletal disease in Box 30.5, gastrointestinal disease in Box 30.6 and skin disease in Box 30.7).

### Functional anatomy and physiology

Visual pathways, innervation of the eye and the control of eye movement are discussed in Chapter 28.

#### Orbit

The orbit is the fat-filled cavity in which the eye is suspended. It is shaped like a square pyramid, the perimeter of its base being the orbital rim. The orbital peristium (‘periorbita’) is continuous with the periosetal layer of cranial dura mater. The dura and arachnoid form the optic nerve sheath, its subarachnoid space containing cerebrospinal fluid in continuity with the third ventricle.

#### Eyelid/orbital septum/conjunctiva

In primary gaze, the eyelids just cover the superior and inferior cornea. The eyelids contain the orbital septum and the tarsal plate.

Within the tarsal plates, modified sebaceous (Meibomian) glands produce an oily surfactant to slow tear evaporation.

The conjunctiva, a mucous membrane, lines the posterior surface of the eyelid, adhering only to the tarsal plates and the sclera/corneal junction. The accessory lacrimal glands provide basal tear production; mucus produced by goblet cells stabilises the tear film by lowering surface tension.

#### Lacrimal gland/lacrimal drainage

The lacrimal gland lies within the periorbita of the anterolateral roof of the orbit. Its secretions (tears) wash away surface irritants and convey emotion. Excess tears drain, via canaliculi in the lids, into the lacrimal sac, nasolacrimal duct and inferior nasal meatus.

### Extraocular muscles

The extraocular muscles (Fig. 30.1) consist of four recti, two obliques and one levator. The recti originate from a circular condensation of periorbita, the annulus of Zinn, which encircles the superior orbital fissure and the optic canal. They extend forwards to insert into the anterior sclera.

The levator palpebrae superioris originates above the optic canal and inserts into the tarsal plate and overlying skin of the upper eyelid. The superior tarsal muscle (Müller’s muscle) originates from the inferior aspect of the levator and also inserts into the tarsal plate.

The superior oblique originates superonasal to the recti, and runs along the roof of the orbit, its tendon passing horizontally through the trochlea at the orbital rim to insert into the anterior sclera.

The inferior oblique originates from the floor of the anterior orbit, just posterior to the lacrimal sac. It turns horizontally, passing beneath the inferior rectus, to insert into the inferior anterior sclera.

### Eye

The optic vesicle develops from the diencephalon. The eye is therefore contiguous with the brain. This is reflected in the three-layer structure of the eye:

- the sclera/cornea, a fibrous outer layer analogous to the meningeal dura
- the choroid, ciliary body and iris (together known as the uveal tract), a vascular middle layer analogous to the pia-arachnoid
- the retina, an inner layer analogous to white matter.

The major structures of the eye are shown in Figure 30.2.

During embryogenesis, overlying ectoderm sinks into the neuroectoderm of the optic vesicle to form the lens vesicle, thus inducing the optic vesicle to form the two-layered optic cup. The inner and outer layers of the optic cup form the neurosensory retina and the retinal pigment epithelium, respectively. The intervening space is continuous with the third
ventricle of the diencephalon. The cilia on the ependymal cells that line the third ventricle are continuous with the cilia on the neurosensory retinal cells, and the latter form the outer segments of the photoreceptors (rods and cones).
30.5 Ophthalmic features of rheumatological/musculoskeletal disease

Rheumatoid arthritis
- Keratoconjunctivitis sicca
- Peripheral ulcerative keratitis (‘corneal melt’)
- Painless episcleritis
- Scleritis and scleromalacia

Seronegative spondyloarthropathies
- Conjunctivitis (chlamydia-associated sexually acquired reactive arthritis, SARA)
- Anterior uveitis

Connective tissue diseases
Dermatomyositis
- Periorbital oedema with violaceous eyelid rash

Sjögren syndrome
- Dry eyes

Treatment effects
- Bull’s eye maculopathy (hydroxychloroquine)
- Viral retinitis (immunosuppression)

Systemic vasculitides
Giant cell arteritis
- Central/branch retinal artery occlusion
- Ischaemic optic neuropathy

Behçet’s disease
- Occlusive retinal vasculitis (posterior uveitis)
- Anterior uveitis with hypopyon

Granulomatosis with polyangiitis
- Scleritis with involvement of adjacent cornea (sclerokeratitis)
- Retro-orbital inflammation
  (see Fig. 26.53)

Polyarteritis nodosa
- Peripheral ulcerative keratitis
- Scleritis

Other/non-specific
- Necrotising scleritis/sclerokeratitis/peripheral ulcerative keratitis
- Anterior ischaemic optic neuropathy
- Extraocular myositis (painful diplopia)

Diseases of bone
Paget’s disease, polyostotic fibrous dysplasia
- Optic neuropathy

Other/non-specific
- Anterior uveitis (adverse effect of bisphosphonates)

30.6 Ophthalmic features of gastrointestinal disease

Malabsorption
- Corneal and conjunctival keratinisation
- Rod photoreceptor loss

Chronic pancreatitis
- Diabetic retinopathy

Inflammatory bowel disease
- Episcleritis
- Non-necrotising scleritis
- Anterior uveitis

Large bowel tumours
- Atypical congenital retinal pigment epithelium hypertrophy (familial adenomatous polyposis)

Inherited liver disease
- Kayser–Fleischer corneal rings, sunflower cataracts (Wilson’s disease)
- Diabetic retinopathy (haemochromatosis)

30.7 Ophthalmic features of skin disease

Rosacea
- Posterior blepharitis

Acne vulgaris
- Dry eye (adverse effect of isotretinoin)

Psoriasis
- Anterior uveitis

Eczema
- Atopic keratoconjunctivitis

Urticaria
- Angioedema

Bullous diseases
- Ocular cicatricial pemphigoid
- Stevens–Johnson syndrome

Alopecia areata
- Eyebrow and eyelash loss

Cutaneous melanoma
- Melanoma-associated retinopathy

Skin tumours
- Eyelid tumours (basal cell carcinoma, squamous cell carcinoma, keratoacanthoma, naevus, melanoma)

Skin infections
- Stye (eyelash folliculitis)
- Acute blepharoconjunctivitis (herpes simplex)
- Chronic conjunctivitis (molluscum contagiosum)

the attachments for the suspensory ligaments of the lens. The ciliary muscle encircles the eye within the ciliary body. Contraction of this muscle relaxes the suspensory ligaments of the lens, bringing near objects into focus.
The iris bows gently forwards as it lies against the lens. It is divided into a pupillary zone, containing the circumferential sphincter pupillae muscle, and a ciliary zone, containing the dilator pupillae.

**Retina**

The retina consists of the neurosensory retina and the retinal pigment epithelium. The two layers are adherent only adjacent to the optic disc and at the edge of the pars plana.

Histologically, the centre of the retina is termed the macula lutea, its yellowish appearance caused by the presence of the xanthophylls (yellow pigments) lutein and zeaxanthin. At the centre of the macula, the neurosensory retina dips to form the fovea.

The single-layered retinal pigment epithelium is highly metabolically active and is essential for the maintenance and survival of the overlying photoreceptors.

The neurosensory retina initiates the visual pathway. Its photoreceptors synapse with radially arranged bipolar neurons, which in turn synapse with circumferentially arranged optic nerve ganglion cells.

‘Horizontal’ and amacrine cells within the plexiform layers modulate neuronal activity between bipolar cells, photoreceptors and the ganglion cells. At the fovea, a one-to-one relationship between cones, bipolar neurons and ganglion cells leads to the highest acuity. In the peripheral retina, many rods converge on to a bipolar neuron, and many bipolar neurons converge on to a ganglion cell, leading to lower acuity. In effect, the peripheral retina conveys black-and-white sentinel vision, alerting the brain to move the higher-acuity colour vision of the fovea into gaze.

Photoreceptors are specialised neurons that cause neurotransmitters to be released in response to light (‘phototransduction’). There are three types of photoreceptors: namely, rods, cones and ganglion cells, the last of which independently respond to blue light, influencing circadian rhythms.

**Lens**

The lens is a transparent flexible structure suspended between the iris and the vitreous. Its flexibility enables objects over a range of distances to be focused on the retina. It has a capsule, a central nucleus and a peripheral cortex. It continues to grow throughout life, becoming less flexible with age.

**Vitreous**

The vitreous gel is 99% water and 1% collagen/hyaluronic acid. The outer edge (cortex) of the vitreous condenses to form the anterior and posterior hyaloid membranes. The base of the vitreous strongly adheres to the ora serrata/pars plana and the optic disc rim, where the internal limiting membrane of the retina is thinnest. Lesser degrees of adhesion occur at the parafoveal retina and along the retinal vessels.

**Blood supply of the orbit/eye**

The main blood supply of the orbit originates from the intracranial internal carotid artery. The ophthalmic artery, the first branch of the internal carotid artery, traverses the subarachnoid space to enter the optic canal.
within the dural sheath of the optic nerve. On leaving the optic canal, it emerges from the dural sheath to course briefly along, and then over, the optic nerve to reach the medial wall of the orbit.

Several arterial circles are formed. The major arterial circle of the iris is formed within the ciliary body by anterior ciliary arteries anastomosing with the posterior ciliary arteries. The pial branches of the optic nerve and the short ciliary arteries join together, as the circle of Zinn, to supply the intraocular optic nerve.

The infraorbital artery, a branch of the maxillary artery, also contributes to the orbital blood supply, in particular the inferior rectus, the inferior oblique and the lacrimal sac.

The orbit is drained by the superior and inferior ophthalmic veins, which converge to drain through the superior orbital fissure into the cavernous sinus.

Investigation of visual disorders

History is the key to diagnosing visual disorders, with examination and investigations used to confirm or refute the expectations formed by the history.

Perimetry

In the era before modern radiology, manual perimetry was utilised as a non-invasive form of ‘neuromaging’. Nowadays, perimetry is largely automated and its main role lies in the monitoring of glaucoma; it also has a lesser role in assessing neuro-ophthalmic disorders. All methods of perimetry are subjective and rely on patient cooperation and mental agility.

Amsler chart

The Amsler chart (Fig. 30.3) is the simplest method of documenting the visual field, and is easy for both patient and clinician to understand and perform. It can be used for all forms of visual field loss but is best suited to follow up the central scotomata of macular disorders, which are often too subtle for other methods of perimetry.

Tangent/Goldmann kinetic perimetry

Manual perimetry methods, such as tangent screen and Goldmann kinetic perimetry, appeal to the non-specialist, as they produce easily interpretable contoured maps of the visual field.

The tangent screen is a piece of black cloth attached to a wall, in front of which the operator introduces moving targets into the patient’s field of view. It retains an important role in the positive identification of functional peripheral field loss (tunnel vision) versus pathological peripheral field loss (funnel vision), although the results are somewhat operator-dependent.

Goldmann perimetry is a mechanical improvement on tangent screen perimetry, which utilises targets of varying size and illumination. An automated version is available.

Automated threshold perimetry

Automated visual fields test the threshold of the eye’s ability to see at various points within the visual field, forming complex outputs that can be stored digitally. Internal quality assurance mechanisms monitor stability of fixation, false positives due to trigger-happy patients and false negatives due to performance fatigue. Many patients need practice before accurate results are obtained; first-time fields are rarely reliable and often show spurious and misleading findings.

Most automated perimetry assessments only central vision. Few neurological disorders start peripherally, the exception being unilateral loss of peripheral field with disease of the anterior pole of the occipital lobe. However, retinal pathology, such as retinal detachment and retinitis pigmentosa, may be missed if reliance is placed on automated perimetry rather than clinical examination.

Visual field defects on perimetry that affect the whole of the superior or inferior half of the visual field need to be differentiated by confrontation into arcuate visual field defects, which affect central field only, and altitudinal field defects, which affect both central and peripheral vision. Arcuate visual field defects localise a lesion to the optic nerve head, whereas a lesion anywhere along the optic nerve can cause an altitudinal defect.

Imaging

See Figure 30.4.

Photography

Digital photography is utilised to document surface anatomy. Colour images are ideal for lesions affecting the skin and cornea. For the retina, however, red-free imaging brings additional benefits, particularly for discriminating red haemorrhages or abnormal new vessels from the red background of the retina. Wide-field imaging is increasingly replacing the need to examine the fundus clinically.

Optical coherence tomography (OCT)

Optical coherence tomography is the optical equivalent of ultrasound, using light rather than sound waves to create its images. It is invaluable, not least for assessing the integrity of the layers of the retina and detecting macular oedema of any cause.

Autofluorescence

The retinal pigment epithelium contains autofluorescent lipofuscin, which can be excited by blue- and green-coloured light and captured by digital imaging.

Increased autofluorescence occurs when there is abnormal accumulation of lipofuscin, as seen with certain inherited retinal dystrophies; excess retinal pigment epithelium metabolic activity, such as at the edge of evolving atrophic macular degeneration; or drug deposition, such as with hydroxychloroquine.

Fundus angiography

Fluorescein angiography is an invasive technique with risks including local extravasation of dye at the site of intravenous injection and anaphylaxis. Currently, its role is limited to the diagnosis of retinal vasculitis, retinal and choroidal neovascularisation, and capillary occlusion. Non-invasive
angiography is now possible using optical coherence tomography, but its applicability is limited by small field of view and inability to demonstrate flow or leakage.

Indocyanine angiography directly images the choroidal circulation and is particularly useful in guiding laser treatment for the choroidal polyps of polypoidal choroidal vasculopathy.

### Ocular ultrasound

The main role of ultrasound is where the retina is obscured; for instance, by cataract or vitreous haemorrhage. It also has an important role in diagnosing choroidal melanoma, based on its distinctive internal reflectivity.

### Visual electrophysiology

Electrophysiology is used to localise disorders to the photoreceptors (electroretinogram), the retinal ganglion cells (pattern electroretinogram) or the optic pathways (visual evoked potential). The site of photoreceptor involvement can be further localised to specific regions of the retina (multifocal electroretinogram) or the macula itself (pattern electroretinogram).

Electrophysiology requires cooperation, correction of refractive errors and the ability to fixate. Voluntary suppression of the electrical responses is possible by simply not focusing on the target. Despite this, it remains the investigation of choice for visual symptoms unexplained by clinical examination.

### Presenting problems in ophthalmic disease

Presenting problems that are ophthalmological manifestations of predominantly neurological disease (e.g. ptosis, diplopia, oscillopsia, nystagmus and pupillary abnormalities) are discussed in Chapter 28.

---

**Watery/dry eye**

The most common cause of a watery eye is a dry eye triggering reflex lacrimation. Patients with dry eye may complain of a foreign body or gritty sensation in the eye or intermittent visual blurring, triggered by reduced blinking, as occurs when reading or when concentrating on a distant object, such as the television.

**Pruritus**

Common causes of itch are an acute allergic response to either airborne allergens or direct contact. A significant proportion of people are allergic to topical chloramphenicol, a first-line treatment for many minor ocular ailments.

**Pain/headache**

The key consideration in deciding whether or not ocular pain and/or headache originates from the eye is whether there is a ciliary flush (red eye) or no ciliary flush (white eye).

**Red eye**

The presence of a ciliary flush in the region of the limbus is a key finding in intraocular causes of pain. The presence of watering or watery discharge is not a discriminatory feature, and over-reliance on this symptom often results in anterior uveitis being misdiagnosed as viral conjunctivitis. The features that are used to distinguish between different causes of red eye are illustrated in Figure 30.5.

**White eye**

In the absence of a ciliary flush (see Fig. 30.5), ocular or periorbital pain is most commonly caused by migraine.
Normal eye anatomy

- Pupil
- Limbus
- Bulbar conjunctiva
- Palpebral conjunctiva

Blepharitis
- Red eyelid margin, symptoms of dry eye, irritation, feeling of something in the eye
- Common in all age groups and may be associated with rosacea or seborrheic dermatitis

Conjunctivitis
- Maximal redness in palpebral conjunctiva, rest of eye may or may not be red
- The discharge of viral conjunctivitis may be hard to differentiate from reflex lacrimation due to photophobia of any cause

Ciliary flush
- Redness first appears at limbus and then spreads outwards
- Early sign of intraocular inflammation, e.g., anterior uveitis, keratitis or acute angle closure glaucoma

Subconjunctival haemorrhage
- Bright red in colour, not sparing of limbus
- Patient often unconcerned, unless part of severe head injury. Usually spontaneous, triggered by Valsalva manoeuvre

Scleritis
- Usually extensive, often bilateral, true extent often hidden by lids
- Unlike episcleritis, this is always painful, often waking the patient at night

Photophobia/glare
- Excessive sensitivity to light, rather than fear of light, usually indicates ciliary muscle spasm due to inflammation in the iris. Common causes are corneal abrasion, acute anterior uveitis and contact lens-related keratitis.
- Occasionally, photophobia can be a symptom of congenital retinal dystrophies, especially cone photoreceptor deficiency. Photophobia may also be a feature of meningitis, usually with accompanying neck stiffness and headache (meningism).
- Glare is a common early feature of cataract, particularly triggered by oncoming car headlights when driving at night. It is a relatively common indication for surgery. It may also be an issue where there is insufficient melanin in the retinal pigment epithelium, e.g., in atrophic age-related macular degeneration, in ocular albinism or following extensive pan-retinal laser therapy. If surgery is not an option, or while surgery is awaited, the symptom of glare may be reduced by wearing a broad-brimmed hat.

Photopsia
- A flickering light sensation is indicative of photoreceptor activity, either through traction, as in the setting of posterior vitreous detachment, or inflammation, as in the setting of autoimmune or paraneoplastic retinopathy. Rarely, photopsia is a symptom of occipital lobe epilepsy, in which case there is usually an accompanying homonymous hemianopia.

Blurred vision
- Blurred vision describes the situation in which patients are able to see what they are looking at, but what they are looking at is out of focus. The most common cause of intermittent blurred vision is dry eye; the most common cause of permanent blurred vision is cataract. If blurred vision is worse in the morning and eases as the day progresses, this suggests macular oedema.

Loss of vision
- In visual loss, patients are no longer able to see all or part of what they are looking at. This may be manifested as either negative visual phenomena, in which part or all of what is being looked at is missing, or positive visual phenomena, in which the object of regard appears to be hidden by something in the way. In positive phenomena, the obstruction is often white or coloured, and may either expand across the visual field or remain in a constant position, sometimes shimmering. The most common cause of transient visual loss is the aura of migraine, which is described in Chapter 28.
- Negative visual phenomena are a cardinal feature of ocular, usually retinal, ischaemia, with complete absence of vision (blackness) occupying part or all of the visual field. Transient ocular ischaemia is usually embolic in nature but is occasionally seen in giant cell arteritis, where it suggests critical optic nerve ischaemia. Permanent monocular negative visual phenomena usually indicate previous optic nerve or retinal infarction. Tiny negative visual phenomena may also be seen in capillary disorders such as diabetic retinopathy, where patchy macular capillary occlusion may, for instance, cause letters to be missing from words on reading.

Fig. 30.5 Common causes of red eye.

Pain on eye movement is a cardinal feature of optic neuritis and scleritis. In optic neuritis the eye is white, whereas in scleritis, except for posterior scleritis, it is red.

Posterior scleritis, in which the visible sclera is white, should be diagnosed only in the setting of positive signs such as disc swelling and exudative retinal detachment, or with confirmation by ocular ultrasound. A more common cause of severe ocular/periocular pain, with associated photophobia and lacrimation, is cluster headache, which is often misdiagnosed as scleritis. Just like scleritis, cluster headache responds to oral glucocorticoids, adding to the diagnostic confusion.

Intermittent, subacute angle closure glaucoma can cause headache, but usually accompanying corneal oedema causes haloes (a form of glare with rainbow colours), elicited by looking at lights or blurring of vision.

Giant cell arteritis (see Ch. 26) occasionally presents with sudden painless visual loss in the absence of raised inflammatory markers. Diagnosis can be made by demonstrating absence of choroidal blood flow on fluorescein angiography.
The clinical features and causes of visual loss (including neurological causes) are summarised in Box 30.8. Some symptoms associated with visual loss require urgent ophthalmological assessment (Box 30.9).

**Distortion of vision**

Distortion is a cardinal symptom of disruption of foveal photoreceptor alignment. The most common cause is choroidal neovascularisation. Less commonly, it can be caused by epiretinal membrane formation, where posterior hyaloid surface scarring causes foveal traction.

Usually with distortion, objects are not only misshapen but also smaller (micropsia), due to the photoreceptors being pulled apart. Macropsia, where objects look bigger than normal, is uncommon. It is sometimes seen in the ‘Alice in Wonderland’ syndrome, a paediatric variant of migraine, where there is altered visual perception of body images.

**Eyelid retraction**

Eyelid retraction is usually caused by inflammatory thyroid eye disease or thyrotoxicosis (see Ch. 20 and Fig. 20.9).

The first muscle to be affected in thyroid eye disease is the inferior rectus. The enlarged muscle tethers the eye and restricts upgaze. Compensatory increased innervation to the superior rectus and the levator palpebrae superioris, as well as direct inflammation, leads to eyelid retraction.

In thyrotoxicosis, increased sympathetic nervous activity leads to bilateral eyelid retraction. This, however, resolves with beta-blockade and treatment of thyrotoxicosis.

Rarely, bilateral eyelid retraction is a sign of dorsal mid-brain pathology (Collier’s sign), where it is accompanied by a supranuclear upgaze palsy and convergence-retraction nystagmus.

### Optic disc swelling and papilloedema

Optic disc swelling (Box 30.10) can be a developmental variant of normal (pseudopapilloedema), a manifestation of optic nerve pathology, or a reflection of more widespread nerve-fibre oedema, as with retinal vein occlusion.

Papilloedema is optic disc swelling occurring as a result of raised intracranial pressure. In this situation obstructed axoplasmic flow from retinal ganglion cells results in swollen nerve fibres, which in turn cause capillary and venous congestion, producing papilloedema. The earliest

![Fig. 30.6 Relative afferent pupillary defect (RAPD)]. The eyes are examined in upgaze. A. Pupils in ambient light. B–E. When a light is swung back and forth to each eye both pupils constrict equally. F. With a left-sided RAPD, the constriction effect of shining the light into the left eye is reduced on both sides, so the pupils dilate each time the light swings to the left eye.

### Optic atrophy

Loss of nerve fibres causes the optic disc to appear pale, as the sclera becomes visible (Fig. 30.8). A pale disc (optic atrophy) follows optic nerve damage; causes include previous optic neuritis or ischaemic damage, long-standing papilloedema, optic nerve compression, trauma and degenerative conditions (e.g. Friedreich’s ataxia, see Box 28.55).

### Specialist ophthalmological conditions

#### Ocular inflammation

Inflammation can affect any part of the eye. In structures in direct contact with the environment, particularly the cornea and the conjunctiva, inflammation is most likely to be caused by infection. In other structures, such as the uveal tract and sclera, inflammation is more likely to be caused by autoimmune conditions, although it may also be a manifestation of infection or malignancy. Although the latter conditions may present with indicative ocular signs, their presence is often appreciated only retrospectively, after failure to respond to immunosuppression.

Most non-infective forms of ocular inflammation are idiopathic; all are more common in the presence of other autoimmune conditions. Some may be directly associated but asynchronous in disease activity, such as the anterior uveitis of ankylosing spondylitis. Others are direct manifestations of an overarching, underlying, inflammatory condition such as the keratocystitis of granulomatosis with polyangitis (formerly known as Wegener’s granulomatosis).

#### Sjögren syndrome

Sjögren syndrome is the archetypal autoimmune disease and its secondary form is associated with a large number of other autoimmune conditions (see Box 26.64). The cardinal features are inflammation of the lacrimal gland, its conjunctival accessory glands and the parotid gland, leading to hyposecretion of tears and saliva. Involvement of the lacrimal gland alone causes keratoconjunctivitis sicca, a syndrome of dry eyes and corneal and conjunctival irritation. Keratoconjunctivitis sicca, however, can also be caused by reduced function of the lacrimal glands and/or lacrimal ducts from other causes.
**Scleritis**

Scleritis is usually accompanied by severe pain, worse on eye movement and often waking the patient through the night. Diagnosis of anterior scleritis is usually straightforward, with the eye showing diffuse or nodular erythema (although it may have to be searched for under the eyelids). Posterior uveitis is often accompanied by reduced vision and oedema of the retina, choroid and extraocular muscles.

White patches of necrosis (pallor) within the erythema are an ominous sign, indicative of systemic vasculitis. Non-necrotising scleritis is commonly idiopathic but may be associated with other autoimmune conditions, particularly rheumatoid arthritis and inflammatory bowel disease. It is also common with herpes zoster ophthalmicus, intracocular involvement being indicated by the involvement of the lateral external nose (Hutchison’s sign).

Necrotising scleritis requires aggressive immunosuppression; non-necrotising scleritis can occasionally be managed by topical glucocorticoids or non-steroidal anti-inflammatory drugs (NSAIDs) but usually requires oral glucocorticoids.

Some patients with recurrent episodes of scleritis, or in whom inflammation is gradual and prolonged, may develop scleral thinning (scleromalacia), revealing the underlying blue choroid.

**Episcleritis**

Episcleritis is a benign self-limiting condition of uncertain aetiology, occasionally associated with other inflammatory disorders. Sectoral redness of the episclera is usual, although nodules can form. Often confused with scleritis, although usually less symptomatic, the diagnostic topical application of phenylephrine turns the inflamed episclera white but has no effect on the redness of scleritis. Treatment is with cold artificial tears, although occasionally topical NSAIDs or topical glucocorticoids are required.

**Uveitis**

Uveitis is an overarching term for inflammation anywhere in the uveal tract, retina or vitreous. It may be classified according to speed of onset, location, specific features, or aetiology [Box 30.11]. Syphilis can cause all forms of uveitis. Active tuberculosis may present with an occlusive vasculitis or serpiginous (snake-like) choroiditis emanating from the optic disc. Latent tuberculosis is a particular concern because treatment of the uveitis with biologics may induce active systemic infection. Furthermore, the type of biologic most commonly used for uveitis, anti-tumour necrosis factor therapy (e.g. adalimumab, infliximab), may trigger demyelination.

The most common form of uveitis is anterior uveitis, which is usually idiopathic and may be associated with other autoimmune conditions, particularly HLA-B27-related spondyloarthopathies (Ch. 26); it is rarely caused directly by infection. Acutely, dilating drops are used to prevent the inflamed iris from sticking to the lens (posterior synechiae) and obstructing the outflow of aqueous fluid, while a tapering dose of topical

**Peripheral ulcerative keratitis**

Peripheral ulcerative keratitis (‘corneal melting’) is an autoimmune disorder affecting the corneal limbus, where it may be accompanied by adjacent scleritis. It may be directly associated with inflammatory disorders in which immune complexes are formed, particularly rheumatoid arthritis, systemic lupus erythematosus and granulomatosis with polyangiitis. Pain and redness are helpful indicators but may not always be present. Systemic immunosuppression is always required but topical glucocorticoids should be used cautiously due to the risk of aggravating keratolysis (corneal thinning). Secondary infection should be prevented with topical antibiotics and attention should be paid to corneal hydration, through the use of artificial tears and lubricants.

More common causes of peripheral corneal ulceration are blepharitis and acne rosacea, which cause ocular irritation rather than frank pain. Hypersensitivity to staphylococcal exotoxin leads to stromal infiltrate adjacent to, but sparing, the limbus (marginal keratitis). Resolution of this self-limiting condition can be assisted by the use of topical chloramphenicol, with or without topical glucocorticoids. Prevention is through management of the underlying condition, usually with ocular lid hygiene for simple blepharitis and metronidazole gel for rosacea.
glucocorticoids, usually over 4–6 weeks, mitigates the local signs and symptoms of the self-resolving inflammation. Inadequate treatment can lead to pupil block glaucoma and cataract. Posterior complications can also develop, predominantly macular oedema, the main cause of visual impairment in all forms of uveitis.

With intermediate uveitis, inflammation occurs at the pars plana, with most symptoms, predominantly floaters, being a result of inflammation of the vitreous base. Unlike anterior uveitis, pure intermediate uveitis is not associated with iris inflammation; instead, white blood cells are seen predominantly in the anterior vitreous, with a lesser amount overspill into the anterior chamber. Treatment is challenging. Topical therapy is ineffective, as it does not penetrate beyond the anterior chamber, but symptoms of floaters are not often sufficient to justify systemic immunosuppression. In some cases, vitritis (vitreous inflammation), or more commonly macular oedema, may cause visual impairment. Occasionally, retinal neovascular proliferation may occur, either as an inflammatory response or as a direct result of capillary occlusion. Intermediate uveitis may be associated with demyelination, sarcoidosis and inflammatory bowel disease. Posterior uveitis tends to present with visual impairment secondary to macular oedema, vitritis or choroiditis. More chronic forms also exist and these tend to present with photopsia, visual field defects or distortion inducing choroidal neovascular membranes.

**Infectious conditions**

**Conjunctivitis**

Conjunctivitis is predominantly caused by bacteria or viruses and is usually self-limiting in 7–10 days. Bacterial conjunctivitis is associated with a purulent discharge and viral conjunctivitis with a watery discharge, the latter often being confused with the photophobia and reflex lacrimation of anterior uveitis. Underlying chlamydial infection should always be considered if there is a persistent thick, mucopurulent discharge.

Allergic conjunctivitis is also common, either as a component of hay fever (allergic rhinitis) or as an allergy to chloramphenicol, which is commonly used to treat conjunctivitis.

Rarely, conjunctivitis may be associated with inflammatory systemic mucus membrane disorders, such as ocular mucus membrane (cicatricial) pemphigoid or Stevens–Johnson syndrome. The secondary effects of loss of conjunctival function can be devastating to the cornea. Other causes of conjunctival scarring include trachoma, chemical burns and orbital radiotherapy.

### Infectious keratitis/corneal ulceration

Inflammation of the cornea should always raise concern about underlying infection (Box 30.12). Central ulceration is always more serious than peripheral, through involvement of the visual axis. Cultures from corneal scraping or biopsy may be required, although much infectious keratitis is treated empirically on the basis of slit, morphology and response to treatment.

Herpes simplex virus type 1 (occasionally type 2) is a common cause of infectious keratitis (Fig. 30.9). All layers of the cornea may be involved: the epithelium in the form of dendritic ulceration; the stroma in the form of white infiltrate and occasionally necrosis; and the endothelium in the form of localised oedema and keratitic precipitates. Loss of corneal sensation is common following herpes simplex keratitis, and occasionally...
neurotrophic keratopathy may result. Epithelial disease is self-limiting but treatment with topical or oral antivirals reduces the risk of stromal involvement and scarring. Stromal and endothelial disease requires additional topical glucocorticoids, but only once any epithelial defect has healed. Herpes simplex keratitis is analogous to herpes labialis; recurrences are therefore common and, if frequent, may warrant long-term oral antivirals. Corneal grafting may be required but the risk of recurrence remains.

Bacteria also cause infectious keratitis, especially following corneal trauma or contact lens misuse. Other risk factors for microbial keratitis include topical glucocorticoids and pre-existing ocular surface disease. Bacterial keratitis has many causes, some of which do not respond to chloramphenicol, so topical quinolones are used as first-line agents. Rarely, the free-living amoeba Acanthamoeba castellanii may be a cause of contact lens-associated keratitis, presenting subacutely and leading to corneal nerve infiltration, keratitis and accompanying scleritis.

Fungal keratitis is the most common cause of infectious keratitis in low income countries, particularly if there has been corneal trauma and contact with soil or plant matter. It is usually caused by Fusarium. Fungal keratitis has no particular distinguishing features and delayed diagnosis is common. If it is suspected, cultures should be undertaken and antifungal treatment, which is hampered by poor corneal penetration of antifungals, started promptly. Corneal transplantation is often required.

**Endophthalmitis**

Endophthalmitis is infection of the anterior and posterior chambers of the eye. It may be exogenous (e.g. from penetrating trauma or following surgery) or, less commonly, endogenous, caused by haematogenous spread of microorganisms within the blood, which gain entry to the eye via the choroid and ciliary body. The causes of endogenous endophthalmitis are therefore the causes of blood-stream infection (Chapter 13). Gram-positive bacteria are most common, followed by Gram-negative bacteria and then fungi, mainly Candida.

Clinical presentation is with visual blurring and/or visual loss, which are usually unilateral. Ocular findings range from a few deposits in the retina/choroid (chorioretinitis) to panendophthalmitis, in which there is a severe inflammatory reaction in both the anterior and posterior chambers. A specific appearance of the retina is described for Candida endophthalmitis, which characteristically causes creamy-white retinal or choroidal lesions (Fig. 30.10). It is vitally important to sample the vitreous, as this may provide the only opportunity to determine the most appropriate therapy. Treatment is with systemic and/or intravitreal antibiotics or antifungal agents, depending on the cause and severity. Vitrectomy may also be required.

**Cataract**

Cataract is permanent opacity of the lens (Fig. 30.11). Globally, untreated cataract is the most common cause of visual impairment.
The normal lens thickens and opacifies with age, and cataract can be detected in more than half the population over the age of 65 (senile cataract). Many ocular and systemic diseases can predispose to cataract formation, the most common being uveitis and diabetes mellitus. Wilson’s disease (hepatolenticular degeneration) causes a characteristic ‘sunflower’ cataract. Excessive exposure to ultraviolet light, ionising radiation and glucocorticoid therapy are also predisposing factors.

The characteristic symptoms of cataract are progressive loss of vision and glare. If these become serious enough to require treatment, surgical intervention will be required, usually in the form of ultrasonic phacoemulsification with intraocular lens (IOL) implant.

Common ophthalmological findings in older people are shown in Box 30.13. Findings and management issues in adolescence and pregnancy are shown in Boxes 30.14 and 30.15, respectively.

### Diabetic eye disease

#### Diabetic retinopathy

Diabetic retinopathy is one of the most common causes of visual impairment in people of working age in high-income countries. The prevalence of diabetic retinopathy increases with the duration of diabetes. Almost all individuals with type 1 diabetes, and most of those with type 2 diabetes, will have some degree of retinopathy after 20 years. Fortunately, most patients develop only mild forms of retinopathy.

**Pathogenesis**

The underlying pathogenesis of diabetic retinopathy is local vascular endothelial growth factor production initiated by hyperglycaemia-induced capillary occlusion. This occlusion stimulates increased production of retinal vascular endothelial growth factor, which not only increases capillary permeability, leading to retinal oedema, but also stimulates angiogenesis, leading to new vessel formation.

**Clinical features**

The initial clinical feature of diabetic retinopathy, capillary occlusion, is visible only on retinal angiography. Capillaries adjacent to the occluded capillary form discrete swellings (microaneurysms), which leak fluid and blood, causing oedema and retinal haemorrhages (Fig. 30.12).

**Management**

• Laser stereomicrophotocoagulation

• Photodynamic therapy

• Panretinal photocoagulation

• Selective laser photocoagulation

• Photodynamic therapy

• Panretinal photocoagulation

• Selective laser photocoagulation

• Photodynamic therapy

• Panretinal photocoagulation

• Selective laser photocoagulation

**Complications**

• Maculopathy

• Vitreous haemorrhage

• Proliferative retinopathy

• Macular oedema

• Central retinal vein occlusion

• Retinal detachments

• Optic disc drusen

• Exudative retinal detachments

• Macular holes

• Macular pucker

**Prevention**

• Good diabetic control

• Regular retinal screening

• Laser therapy or drugs to decrease retinal neovascularisation

**Surgical treatment**

• Vitrectomy

• Pars plana vitrectomy

• Membrane peeling

**Clinical course**

• Regressed

• Stable

• Progressing

• Severe

**Natural history**

• Progression

• Regression

• Stability

**Prophylactic treatment**

• Laser photocoagulation

• Early laser photocoagulation

• Late laser photocoagulation

**Prognosis**

• Good

• Fair

• Poor

**References**

### 30.14 Medical ophthalmology in adolescence

**Inherited conditions**

- Stargardt disease: autosomal recessive macular dystrophy that commonly presents in adolescence/early adulthood, causing significant bilateral impairment of central vision.

**Developmental anomalies**

- Pathological myopia: due to elongated ocular axial length rather than refractive index of cornea and lens. Increased risk of retinal detachment and choroidal neovascular membrane formation.

- Optic disc drusen: come to prominence during adolescence and usually first detected during routine examination. Often mistaken for papilloedema, particularly in the setting of coincidental daily headache.

- Amblyopia: occasionally detected after the age of 7 years, particularly in the absence of pre-school screening, when it is unlikely to respond to patching of the other eye.

- Keratoconus: presents with increasing astigmatism (distortion of vision due to abnormal corneal topography). Hard contact lenses are the mainstay of therapy. Further progression may be prevented through ‘cross-linking’ surgery.

**Deterioration of existing conditions**

- Diabetic retinopathy: in type 1 diabetes, retinopathy usually first presents at least 5 years after diagnosis, which often coincides with adolescence. Puberty may accelerate progression. Greatest risk is disengagement with diabetes care, including retinal screening, significantly increasing later presentation with advanced symptomatic retinopathy.

- Adult manifestations of retinopathy of prematurity: clinical features depend on the type of treatment used in the neonatal period and include retinal detachment, angle closure glaucoma, severe myopia and cataract.

**Sexual activity**

- Chlamydia conjunctivitis: onset of sexual activity may lead to this ocular condition, which may be associated with reactive arthritis (SARA). Untreated coexistent genital tract infection may cause infertility.

**Transition to adult services**

- Neurofibromatosis type 1.

- Optic nerve astrocytoma/glioma: often develops in late childhood or early adolescence.

**Sports medicine**

- Contact sports: eye protection is important for all, especially if there is only one functional eye, e.g., with amblyopia.

Clinically, microaneurysms appear as isolated red dots, the capillaries being too small to visualise. At the edge of any leaking fluid, lipids precipitate out to form exudate, like the tidemark of the sea.

In turn, capillaries with microaneurysms also occlude, their microaneurysms turning white before disappearing entirely from clinical view.
As more and more capillaries occlude, larger patches of retinal ischaemia form, leading to sufficient vascular endothelial growth factor production to induce the growth of new vessels at the border of diseased and undiseased retina.

Within patches of retinal ischaemia, diseased remnants of partially perfused capillaries form intra-retinal microvascular abnormalities (IRMAs) and retinal veins develop multiple diffuse swellings (venous beading). These signs are best seen on fluorescein angiography.

New vessels and their glial tissue (like a cabbage leaf) grow from retinal veins, through the overlying internal limiting membrane into the vitreous, triggering local inflammation and contracting scars. The vitreous is strongly adherent to the pars plana. It pulls back on the new vessel, triggering further bleeding, growth, inflammation and scarring. If the scarring is sufficient, then tractional retinal detachment and complete blindness may occur.

Other retinal lesions, not unique to capillary occlusion, are also seen in diabetic retinopathy. These include flame haemorrhages and cotton wool spots (soft exudates). Flame haemorrhages are horizontal streaky haemorrhages in the retinal nerve-fibre layer. They are also seen in any severe anaemia, e.g. bacterial endocarditis and leukaemia. Cotton wool spots are also situated in the nerve-fibre layer and are usually most numerous nasal to the optic disc, where the nerve fibres crowd together. They are also seen in accelerated hypertension, after severe hypoglycaemia and occasionally in giant cell arteritis. A cotton wool spot combined with an enclosing flame haemorrhage is termed a Roth spot. Roth spots have traditionally been associated with endocarditis, although they may be seen with any cause of a flame haemorrhage.

Management of proliferative diabetic retinopathy

If untreated, proliferative retinopathy eventually causes severe visual impairment through recurrent vitreous haemorrhage and retinal detachment. Pan-retinal laser photocoagulation therapy is extremely effective at preserving vision, if applied before complications set in.

Historically, laser therapy was used empirically to ablate the retina extensively outside the macula. However, this caused secondary optic atrophy and night blindness (nyctalopia), which interfered with the ability to drive. Modern application of laser is lighter, more tailored to the sites of underlying capillary ischaemia and relatively free of side-effects, only occasionally resulting in loss of the ability to drive. In the UK there is a requirement to inform the driver licensing authority if retinopathy is (or has been) present in both eyes, irrespective of treatment history.

Intravitreal injections of anti-vascular endothelial growth factor (e.g. ranibizumab, aflibercept, bevacizumab) also cause temporary regression of proliferative retinopathy, whereas, after pan-retinal laser therapy, background and proliferative types of retinopathy regress permanently. If both eyes have been treated with laser, patients can be safely discharged to a retinal screening programme.

Management of diabetic macular oedema

Traditionally, oedema seen on slit-lamp biomicroscopy was categorised according to three patterns of leakage elucidated from fluorescein angiogram studies:

- focal leakage from microaneurysms
- diffuse leakage from diseased capillaries
- ischaemia (no leakage) from thrombosis of the perifoveal capillaries.

Laser was applied, either directly on leaking microaneurysms or empirically by placing a grid of burns on the affected macula, to reduce leakage. The main aim was to treat oedema before the fovea was affected, as laser therapy for oedema affecting the fovea was never particularly effective.

However, retinal screening programmes have demonstrated that extrafoveal macular oedema often resolves spontaneously, and the introduction of intravitreal injection therapy, which rescues vision in 50% of those treated regardless of the mechanism of oedema, has led to
a paradigm shift in management. Now, rather than laser treatment of asymptomatic oedema that does not involve the centre of the fovea, the emphasis has shifted to treating those who are symptomatic from centre-involving foveal oedema (confirmed on optical coherence tomography) with anti-vascular endothelial growth factor injections. Although this method of treatment is more effective, monthly injections may be required indefinitely.

**Prevention**

There is a clear relationship between glycaemic control and the incidence of diabetic retinopathy. A combination of good glycaemic and blood pressure control also slows the progression of retinopathy.

When blood glucose is rapidly lowered in patients with type 1 diabetes, however, there can be a transient deterioration of retinopathy, predominantly in the form of cotton wool spot formation, but occasionally triggering new vessel formation. The trigger is believed to be increased systemic insulin growth factor release, which is most likely to occur with sudden correction of eating disorders or reinitiation of insulin therapy in those who miss out injections, often to induce weight loss. This often occurs during hospitalisation for other reasons.

Although, ideally, any improvement in glycaemic control should be gradual, in many circumstances this is hard to achieve, particularly if the patient suddenly decides to comply with treatment, leading to dramatic improvement in glycaemic control.

**Screening**

Systematic screening for asymptomatic proliferative retinopathy has been shown to be cost-effective. It has led to the introduction of population-based screening programmes in the UK and other countries, where health care is funded centrally. There is little evidence that screening asymptomatic patients for macular oedema is cost-effective, although a by-product of screening is that suspected macular oedema has become the most common reason for referral from retinal screening to ophthalmology.

Although hand-held ophthalmoscopy has been shown to have poor sensitivity compared to examination by slit-lamp biomicroscopy or retinal photography, any form of screening is better than none where resources are scarce. Currently, optical coherence tomography is being added to the screening pathway to reduce false-negative referrals for macular oedema.

Historically, annual screening has been advocated. However, evidence now indicates that patients with repeated normal screens, particularly those with type 2 diabetes, can be safely screened every 2 years.

In pregnancy, the placenta is a source of angiogenic growth factors. For this reason, although the risk of developing significant retinopathy during pregnancy remains low, pregnant women should be screened every trimester until the placenta is delivered.

**Other causes of visual loss in people with diabetes**

Around 50% of visual loss in people with type 2 diabetes results from causes other than diabetic retinopathy. These include cataract, age-related macular degeneration, retinal vein occlusion, retinal arterial occlusion, non-arteritic ischaemic optic neuropathy and glaucoma. Some of these conditions are to be expected in this group, as they relate to cardiovascular risk factors (e.g. hypertension, hyperlipidaemia and smoking), all of which are prevalent in people with type 2 diabetes.

In diabetes, metabolic changes in the lens (which are not yet fully elaborated) cause premature and/or accelerated cataract formation. A rare type of ‘snowflake’ cataract occurs in young patients with poorly controlled diabetes. This does not usually affect vision but tends to make fundal examination difficult. The indications for cataract surgery in diabetes are similar to those in the non-diabetic population, but an additional indication in diabetes is when adequate assessment of the fundus and/or retinal laser therapy becomes impossible.

**Retinal vascular occlusion**

**Retinal vein occlusion (thrombosis)**

Retinal vein occlusion is an important vascular cause of visual impairment, visual loss resulting from macular oedema or occasionally from neovascularisation, both of which are managed in a similar way to diabetic macular oedema or proliferative diabetic retinopathy.

Although pathogenesis of retinal vein occlusion is not fully understood, the most common mechanism is believed to be compression of a vein by an adjacent arteriosclerotic artery. Retinal veins are unusual in that, where the arteries and veins cross over each other, they share a common outer layer (tunica adventitia). This means that arteriosclerotic thickening of an artery leads directly to compression of the adjacent vein (arteriovenous nipping).

A less common cause of retinal vein occlusion is inflammation of the retinal vein (periphlebitis), also called retinal vasculitis (unlike systemic vasculitis, the arterial system is not involved). Periphlebitis should be suspected in younger patients and in patients with no obvious risk factors for arteriosclerosis. Diagnosis is made by fluorescein angiography and treatment is with systemic immunosuppression, with or without adjunctive intravitreal therapy.

Retinal vein occlusion is associated with systemic hypertension and may rarely result from hyperviscosity due to a myeloproliferative disorder, multiple myeloma, Waldenström’s macroglobulinaemia or leukaemia. Glaucoma is associated with retinal vein occlusion but whether this is a direct cause or merely a comorbidity in older people is not known.

Clinical presentation is with unilateral painless loss of central vision (central retinal vein thrombosis) or an area of peripheral vision (branch retinal vein thrombosis). Fundoscopy features include flame haemorrhages, cotton wool spots, macular oedema and a swollen optic disc (Fig. 30.13).

The management of retinal vein occlusion is twofold: management of the underlying aetiology and management of the consequences of retinal vein occlusion. Where an underlying risk factor for arteriosclerosis is clearly present secondary prevention measures should be commenced. However, the role of secondary prevention of arteriosclerosis in isolated retinal vein occlusion, although common practice by some, remains controversial.

**Retinal artery occlusion**

Retinal artery occlusion is usually an embolic phenomenon. Common predisposing factors are therefore (predominantly carotid) arteriosclerosis, valvular heart disease, arrhythmias and infective endocarditis. The next most common cause is vasculitis, mainly giant cell arteritis.

![Fig. 30.13 Central retinal vein occlusion (thrombosis), showing flame haemorrhages, cotton wool spots, macular oedema and a swollen optic disc. Courtesy of Aberdeen Royal Infirmary.](image-url)
Retinal artery occlusion presents with painless unilateral visual loss, the extent and location of which depend on whether there is a central occlusion or a branch occlusion (peripheral occlusions may be asymptomatic). Transient occlusion of the internal carotid or ophthalmic artery causes transient visual loss, or amaurosis fugax. The typical fundoscopic finding in a central occlusion is a transient pale retina with a ‘cherry-red’ spot at the macula, the appearance developing over an hour or so after the occlusion (Fig. 30.14). In branch occlusions there is no cherry-red spot and the retinal pallor is regional.

**Age-related macular degeneration**

Age-related macular degeneration is the most common cause of visual impairment in high income countries. There are two basic forms: atrophic (dry) and neovascular (wet). The underlying mechanism is dysfunction of the retinal pigment epithelium, leading to overlying photoreceptor death. Choroidal neovascularisation, growing under and into the overlying retina, may occur, distorting the anatomy of the photoreceptors and ending in scar formation. Both forms are preceded by deposits under the retinal pigment epithelium ('drusen'), often followed by the development of focal areas of macular hypo- and hyperpigmentation, where diseased retinal pigment epithelial cells have precipitated their pigment (age-related maculopathy).

The atrophic form presents with gradual onset of central visual blurring, accompanied, to a lesser degree, by visual distortion. Large (geographic), central patches of atrophy are seen with areas of adjacent hyperpigmentation. In the neovascular form, sudden onset of central distortion, progressing within weeks, is the predominant symptom. Apart from age, the main risk factor appears to be smoking.

The advent of anti-vascular endothelial growth factor injectors has led to effective therapy for the neovascular form, in many but not all. Unfortunately, treatment is expensive and requires considerable financial and staff resources to treat in timely fashion; delayed treatment can lead to irreversible visual loss. For whichever type, whether treatable or not, visual rehabilitation, through the use of appropriate magnifiers, alteration in lighting and specialised adaptation of everyday living objects, remains important adjunctive therapy.

Multiple Choice Questions

30.1 Intraocular pressure is determined by the balance between the rate of production of aqueous humour and the rate of outflow through the trabecular and uveoscleral outflow. Which part of the ciliary body is responsible for producing aqueous humour?

A. Zonular fibres  
B. Pars plana  
C. Anterior non-pigmented ciliary epithelium  
D. Posterior pigmented ciliary epithelium  
E. Ciliary muscle

Answer: C.

The ciliary body is part of the uvea, which comprises the iris, ciliary body and choroid. The ciliary body lies between the iris and the more posterior choroid. It is located in the eye circumferentially beneath the corneal limbus. Anteriorly, its non-pigmented ciliary processes actively secrete the majority of aqueous fluid mainly through Na+/K+-ATPase pump activity. This fluid passes forward through the pupil into the anterior chamber. A small amount of aqueous humour is secreted passively. This is a process of ultrafiltration and diffusion, dependent on capillary hydrostatic pressure, oncotic pressure and IOP.

30.2 All of the following extraocular muscles arise from the orbital apex except:

A. Medial rectus  
B. Inferior oblique  
C. Lateral rectus  
D. Inferior rectus  
E. Superior oblique

Answer: B.

Inferior oblique originates in the anterior orbit from the orbital surface of the maxillary bone in the anterior orbital floor. The rectus muscles originate from a tendinous ring, the ‘annulus of Zinn’, at the orbital apex and course forwards to attach to the anterior aspect of the globe. The superior oblique originates just superiorly and nasal to the origin of superior rectus at the orbital apex. It courses forwards passing through a pulley system, the trochlear, and inserts onto the posterior globe.

30.3 A 23-year-old man presents with a 2-day history of a red, painful, photophobic left eye. He describes a burning sensation. He has no past ocular history, does not wear contact lenses and is usually fit and well. A drop of fluorescein is instilled into his eye and on examination with blue light a branching dendritic lesion is seen. What is the most appropriate treatment for this condition?

A. Topical aciclovir  
B. Oral aciclovir  
C. Topical steroid  
D. Topical antibiotics  
E. Topical lubricants

Answer: A.

A dendritic lesion in the absence of a history of contact lens wear is typical of herpes simplex keratitis. Débridement of the area with a viral swab has a two-fold benefit: firstly it reduces the viral load and secondly, if it is a first presentation of herpetic eye disease it is important to establish a formal diagnosis. This is followed by treatment with topical aciclovir until the lesion is resolved. Some types of herpetic eye disease including recurrent presentations benefit from treatment with oral aciclovir. Topical steroid is absolutely contraindicated in the absence of antiviral cover. Topical antibiotics or lubricants will not help because the aetiology is viral.

30.4 A 28-year-old man has been referred to eye casualty complaining of a red, watering, painful and photophobic eye for the last 6 days. He is not a contact lens wearer and has been using chloramphenicol ointment from the chemist which is not improving the symptoms. He has no significant medical history. Examination is challenging due to the degree of photophobia. His eye is very injected with ciliary flush and the pupil reacts sluggishly. What is the most common cause of this condition?

A. Herpesvirusae infection  
B. Sarcoidosis  
C. Angle closure glaucoma  
D. HLA-B27 seropositivity  
E. Idiopathic

Answer: E.

This is a typical presentation of anterior uveitis. Idiopathic anterior uveitis is the most common form. The aetiology is unknown but could be related to cross-reactivity with particular microbial antigens. Systemic associations of anterior uveitis include HLA-B27 spondyloarthropathies, anklyosing spondylitis, psoriatic arthritis and reactive arthritis as well as Crohn’s disease and ulcerative colitis. Infective causes include Herpesvirusae herpes simplex and varicella zoster, syphilis, TB and Lyme disease. Other associated systemic conditions include sarcoidosis, juvenile idiopathic arthritis, Behçet’s disease and SLE. Less common causes include drug-induced, especially anti-cancer drugs, haematological malignancy and even recent tattoos. It is therefore important to take a full systemic history, social and drug history to look for these associations. It would be almost unheard of to diagnose angle closure glaucoma in a man of this age and a feature against this is the presence of a reactive pupil, albeit sluggish.

30.5 A 35-year-old woman has noticed a change in the appearance of her right eye for the past 5–6 weeks. She describes a slight deterioration in vision and the eye has been aching, which is exacerbated with eye movement. Past medical history includes one spontaneous vaginal delivery and diet-controlled gestational diabetes. She takes the oral contraceptive pill. On examination visual acuity is 6/12 in the right eye, 6/6 in the left. She has a full range of eye movements but complains of a tugging sensation on upgaze. Her colour vision, visual field testing and pupillary responses are normal. Externally her eyelids are not swollen or red, the eyes are both white. She has 2mm of proptosis on the right side and you can see 1 mm of sclera above the cornea. Her basic observations are all within range. What is the most likely diagnosis?

A. Orbital cellulitis  
B. Thyroid eye disease  
C. Cavernous sinus thrombosis  
D. Idiopathic orbital inflammatory syndrome  
E. Optic neuritis

Answer: B.

Thyroid eye disease is the most common cause of both unilateral and bilateral proptosis in adults. Typical features include ocular pain at rest, which is exacerbated with eye movements (gaze-evoked pain), swelling and redness of the lids, conjunctiva, plica and caruncle, double vision and proptosis. Sight-threatening complications of thyroid eye disease occur secondary to the increased orbital pressure. If this damages the optic nerve it is termed dysthyroid optic neuropathy or if orbital swelling causes proptosis so severe that the eyelids cannot close this may result in corneal exposure keratopathy, a potentially sight- and eye-threatening condition.
It is always important to consider orbital cellulitis in cases of proptosis but this would present more acutely with severe lid swelling, oedema, pain and usually with systemic manifestations including pyrexia. The differential diagnosis of proptosis is extensive, including trauma, vascular lesions such as carotid-cavernous fistulas or cavernous sinus thrombosis, neoplastic lesions and inflammatory conditions. Optic neuritis can present with reduced visual acuity and retrobulbar pain classically exacerbated with eye movement. However optic neuritis is not associated with proptosis, additionally optic nerve function, which includes colour vision, visual field testing and pupillary responses, would be abnormal.

30.6 A 73-year-old man attends his optician. He was hospitalised following a stroke a few months ago causing weakness in his left face, arm and leg. Although his mobility has improved he reports his vision on the left is not any better. He wears spectacles for both near and distance and wanted these updating to improve his vision. His past medical history includes atrial fibrillation, hypertension, type 2 diabetes, COPD, hypercholesterolaemia and benign prostatic hyperplasia. The optician performs visual field testing. What is the most likely pattern of visual field loss?

A. Left monocular loss  
B. Right homonymous hemianopia  
C. Left homonymous hemianopia  
D. Bitemporal hemianopia  
E. Left superior altitudinal visual field defect

Answer: C.

The left-sided hemiparesis described would be caused by a stroke in the right cerebral hemisphere. The same pathology would affect the right optic radiation. Fibres representing the left temporal hemifield and the right nasal hemifield travel in the right optic radiation. Damage in this area would therefore cause a left homonymous hemianopia. This can be preferentially superior or inferior depending on the particular location of the stroke. Patients may interpret these symptoms and describe it as visual loss from one eye, which is why confrontational visual fields are an important part of a cranial nerve exam. Bitemporal hemianopia is classically caused by pituitary or other chiasmal pathology. Monocular altitudinal visual field defects are caused by pathology affecting the optic nerve or retina.

<th>Psychiatry and the law 1260</th>
</tr>
</thead>
</table>
Psychiatric disorders have traditionally been considered as ‘mental’ rather than as ‘physical’ illnesses. This is because they manifest with disordered functioning in the areas of emotion, perception, thinking and memory, and formerly had no clearly biological basis. However, as biochemical and structural abnormalities of the brain are identified in an increasing number of psychiatric disorders, and psychological and behavioural factors are identified in many medical illnesses, the distinction between mental and physical illness has become questionable.

The World Health Organization (WHO) periodically publishes its International Classification of Disease (ICD), which provides definitions for every recognised clinical condition. The 10th Revision (ICD-10) comprises 22 chapters. The diagnoses listed in Chapter V, ‘Mental and behavioural disorders’ (Box 31.1), are used by psychiatrists around the world in everyday clinical practice and it is these conditions that provide the focus for this chapter.

Psychiatric disorders are among the most common of all human illnesses. The WHO’s Global Burden of Disease study found ‘Mental, neurological and substance misuse disorders’ to be the leading cause of ‘Years Lost to Disability’ (YLDs), accounting for almost 20% of global YLDs, with anxiety and mood disorders alone accounting for over 10%. As with most clinical conditions, the prevalence of mental disorders varies with the setting. In the general population, depression, anxiety disorders and adjustment disorders are most common (>10%) and psychosis is rare (<2%); in acute medical wards of general hospitals, organic disorders such as delirium are very common, with prevalence highest among sick, older patients; in specialist general psychiatric services, psychoses are the most common disorders (Box 31.2).

### Clinical examination

As in other areas of medicine, the psychiatric assessment comprises a structured clinical history and examination followed by appropriate investigations. However, psychiatric assessment differs from a standard medical assessment in the following ways:

- There is greater emphasis on the history and relatively less reliance on investigations.
- A large part of the clinical examination component is conducted as the history is being taken rather than as a discrete set of procedures afterwards.
- It commonly includes the interviewing of an informant, usually a relative or friend who knows the patient, especially when the illness affects the patient’s ability to give an accurate history.

A full psychiatric history (Box 31.3) incorporating a detailed mental state examination may take an hour or more because of its complexity. A brief mental state examination, usually taking no more than a few minutes (see below), should be part of the assessment of all patients, not merely those deemed to have psychiatric illnesses.

### The psychiatric interview

The aims of the interview are to:

- establish a therapeutic relationship with the patient
- elicit the symptoms, history and background information (Box 31.3)
- examine the mental state
- provide information, reassurance and advice.

#### 31.3 How to structure a psychiatric interview

<table>
<thead>

</tr>
<tr>
<td><strong>Previous personality</strong></td>
</tr>
<tr>
<td>• The patterns of behaviour and thinking that characterise a person, including their relationships with other people and reactions to stress (useful information may be obtained from an informant who has known the patient well for many years)</td>
</tr>
</tbody>
</table>

### The mental state examination

The mental state examination (MSE) is a systematic examination of the patient’s thinking, emotion and behaviour. As with the clinical examination in other areas of medicine, the aim is to elicit objective clinical signs. While many aspects of the patient’s mental state may be observed as the history is being taken, specific enquiries about important features should always be made.

#### General appearance and behaviour

Any abnormalities of alertness or motor behaviour, such as restlessness or retardation, should be noted. The level of consciousness should be determined, especially in the assessment of possible delirium.

#### Speech

Speed and fluency should be observed, including slow (retarded) speech and word-finding difficulty. ‘Pressure of speech’ describes rapid speech that is difficult to interrupt.

#### Mood

This can be judged by facial expression, posture and movements. Patients should also be asked if they feel sad or depressed and if they lack ability to experience pleasure (anhedonia). Are they anxious, worried or tense? Is mood elevated with excess energy and a reduced need for sleep, as in (hypo)mania?

#### Thoughts

The content of thought can be elicited by asking ‘What are your main concerns?’ Is thinking negative, guilty or hopeless, suggesting depression? Are there thoughts of self-harm? If so, enquiry should be made about plans. Are patients excessively worried about many things, suggesting anxiety? Do they think that they are especially powerful, important or gifted (grandiose thoughts), suggesting mania?

The form of thinking may also be abnormal. In schizophrenia, patients may display loosened associations between ideas, making it difficult to follow their train of thought. There may also be abnormalities of thought possession, when patients experience the intrusion of alien thoughts into their mind or the broadcasting of their own thoughts to other people.

#### Abnormal beliefs

A delusion is a false belief, out of keeping with a patient’s cultural background, which is held with conviction despite evidence to the contrary.

#### Abnormal perceptions

Illusions are misperceptions of real stimuli. Hallucinations are sensory perceptions that occur in the absence of external stimuli, such as hearing voices when no one is present.

#### Cognitive function

Cognitive function has many components: memory, concentration, visuospatial abilities, executive function and so on. In most cases, a brief assessment of orientation (person, place and time – the patient is asked their name, age, date of birth, what building they are in, the current date and day of the week) and attention (‘serial 7s’ – the patient is asked to subtract 7 from 100 and then 7 from the answer, and so on) is sufficient to exclude clinically significant cognitive impairment. Where there is reason to suspect cognitive impairment, a standardised screening tool should be used. In delirium, cognitive impairment typically fluctuates over time so may be missed by a single assessment.

The Montreal Cognitive Assessment (MoCA) is a useful screening questionnaire that covers all the main domains of cognitive function (Fig. 31.1). It is designed to be easy to use and is freely available online in many different languages. Another widely used screening test is the Mini-Mental State Examination (MMSE), although this is subject to copyright, unlike the MoCA. The Addenbrooke’s Cognitive Examination – 3rd edition (ACE–III) offers a more comprehensive assessment and brief training courses for clinicians wishing to use it. These resources are available online (see ‘Further information’).

#### Patients’ own understanding of their symptoms

Patients should be asked what they think their symptoms are due to and whether they warrant treatment. The failure of a patient to understand their own symptoms is referred to as ‘lack of insight’. Psychotic patients characteristically have lack of insight and fail to accept that they are in need of treatment.

### Investigations in medical psychiatry

In many areas of medicine, laboratory or radiological tests play a central role in diagnosis. Such tests are often performed in psychiatry but are typically used to exclude non-psychiatric illness rather than to confirm a psychiatric diagnosis. For example, in a patient presenting with symptoms of anxiety it may be appropriate to check thyroid function to exclude thyrotoxicosis as a cause of their symptoms. Specific investigations are recommended in certain psychiatric conditions such as
dementia, delirium, substance misuse and eating disorders, as shown in Box 31.4. Further details of each of these disorders are discussed later in the chapter.

### Functional anatomy and physiology

Most psychiatric disorders result from a complex interplay between psychological, social, environmental and genetic factors. Each of these factors may play a role in predisposing to, precipitating or perpetuating a disorder (Box 31.5).

#### Biological factors

**Genetic**

Genetic factors play a predisposing role in many psychiatric disorders, including schizophrenia and bipolar disorder. However, while some
disorders, such as Huntington’s disease, are due to mutations in a single gene, the genetic contribution to most psychiatric disorders is polygenic in nature and mediated by the combined effects of several genetic variants, each with modest effects and modulated by environmental factors.

### Brain structure and function

Brain structure is grossly normal in most psychiatric disorders, although abnormalities may be observed in some conditions, such as generalised cerebral atrophy in Alzheimer’s disease and enlarged ventricles with a slightly decreased brain size in schizophrenia. Functioning of the brain, however, is commonly altered due to changes in neurotransmitters such as dopamine, noradrenaline (norepinephrine) and 5-hydroxytryptamine (5-HT, serotonin). Functional differences in specific areas of the brain are increasingly being recognised using advanced imaging techniques.

For example, postmortem emission tomography (PET) studies of dopamine ligand binding in schizophrenia have consistently demonstrated increased dopamine synthesis in the striatum, even in untreated patients, while a smaller body of PET evidence points towards reductions in 5-HT transporter binding in the mid-brain and amygdala in depression.

Pattern classification approaches to structural magnetic resonance imaging (MRI) data can accurately predict the development of schizophrenia in at-risk populations, and generalised grey matter loss over time is a poor prognostic guide. Increased anterior cingulate activity in depression is a consistent predictor of good response to both antidepressants and cognitive behaviour therapy. While these and other imaging techniques show potential as diagnostic, prognostic and therapeutic aids, they remain research tools at the present time.

It is also increasingly clear that psychiatric disorders are associated with disruptions in neuronal systems rather than single sites. These can be characterised using diffusion tensor imaging (DTI) of white-matter projection fibres and resting-state/task-based functional MRI (fMRI) studies of inter-regional connectivity. For example, DTI has shown reduced white-matter density in limbic (‘emotional’) system tracts, such as the fornix and cingulum, in many disorders. Resting-state fMRI studies consistently identify ‘default mode’, salience and executive control networks of interconnected neuronal populations for certain mental activities. These pathways are implicated in several psychiatric disorders but, as yet, in non-specific ways.

### Psychological and behavioural factors

#### Early environment

Early childhood adversity, such as emotional deprivation or abuse, predisposes to most psychiatric disorders, such as depression, eating disorders and personality disorders in adulthood.

#### Personality

The relationship between personality and psychiatric disorder can be difficult to assess because the development of psychiatric disorder can impact on a patient’s personality. Some personality types predispose the
Social isolation is the most common cause. Just because a person is old and frail does not mean that depression is ‘to be expected’ and that it should not be treated.

Behaviour
A person’s behaviour may predispose to the development or perpetuation of a disorder. Examples include excess alcohol intake leading to dependence, dieting in anorexia or persistent avoidance of the feared situation in phobia.

Social and environmental factors

Social isolation
The lack of a close, confiding relationship predisposes to some psychiatric disorders, such as depression, and this may be particularly relevant in older adults where social isolation is common (see Box 31.6). As well as predisposing to psychiatric disorders the reduced social support that results from having a psychiatric disorder may also act to perpetuate it.

Stressors
Social and environmental stressors often play an important role in precipitating psychiatric disorder in those who are predisposed, such as trauma in post-traumatic stress disorder, losses (such as bereavement) in depression, and events perceived as threatening (such as potential loss of employment) in anxiety.

31.6 Medical psychiatry in old age

- Organic psychiatric disorders: especially common, so cognitive function should always be assessed; if impaired, an associated medical condition or adverse drug effect should be suspected.
- Disturbed behaviour: delirium is the most common cause.
- Depression: common. Just because a person is old and frail does not mean that depression is ‘to be expected’ and that it should not be treated.
- Self-harm: associated with an increased risk of completed suicide.
- Medically unexplained symptoms: common and often associated with depressive disorder.
- Loneliness, poverty and lack of social support: must be taken into consideration in management decisions.

individual to develop a psychiatric disorder, however; for example, an obsessional (‘anankastic’) personality increases the risk of obsessive-compulsive disorder. A disordered personality may also perpetuate a psychiatric disorder once it is established, leading to a poorer prognosis.

Investigations
Abnormalities in routine biochemistry and haematology can support the diagnosis of alcohol excess (such as the finding of a raised mean cell volume (MCV) and/or raised γ-glutamyl transferase (GGT)), but such tests are abnormal in only half of problem drinkers; consequently, normal results on these tests do not exclude an alcohol problem. When abnormal, these measures may be helpful in challenging denial and monitoring treatment response. Transient elastography (also known as FibroScan) is an ultrasound-based technique that measures fibrosis and steatosis. It is used in specialist services to complement information derived from tests of MCV and GGT.

Management
The prevention and management of alcohol-related problems are discussed later in this chapter.

Substance misuse
The misuse of drugs of all kinds is also widespread. As well as the general headings listed for alcohol problems in Box 31.23, additional problems may occur in association with substance misuse (Box 31.7). These can be broken down into two broad categories:

- problems linked with the route of administration, such as intravenous injection
- problems arising from pressure applied to doctors to prescribe the misused substances.

Assessment and management are described later in this chapter in the section on substance misuse.

Delusions and hallucinations
Delusions and hallucinations are abnormal beliefs and perceptions that have no rational basis. They are often due to psychiatric illness but can be secondary to substance misuse, physical illness or neurological disorders, such as epilepsy.

Delusions
A delusion is a false belief, out of keeping with a patient’s cultural background, which is held with conviction despite evidence to the contrary. It is common to classify delusions on the basis of their content. They may be:

- persecutory – such as a conviction that others are out to harm one
- hypochondriacal – such as an unfounded conviction that one has cancer
- grandiose – such as a belief that one has special powers or status
- nihilistic – such as ‘My head is missing’, ‘I have no body’ or ‘I am dead’.

31.7 Substance misuse

Complications arising from the route of use

Intravenous
- Local: abscesses, cellulitis, thrombosis
- Systemic: bacterial (endocarditis), viral (hepatitis, human immunodeficiency virus (HIV))

Nasal ingestion
- Erosion of nasal septum, epistaxis

Smoking
- Oral, laryngeal and lung cancer

Inhalation
- Burns, chemical pneumonitis, rashes

Pressure to prescribe misused substance
- Manipulation, deceit and threats
- Factitious description of illness
- Malingering

Presenting problems in psychiatric illness

Delirium
Delirium is a medical disorder that is common in older adults and in patients in high-dependency and intensive care units. The causes, assessment and management of delirium are described in Chapter 14.

Alcohol misuse
Misuse of alcohol is a major problem worldwide. It presents in a multitude of ways, which are discussed later on in this chapter and summarised in Box 31.23. In many cases, the link to alcohol is obvious; in others, it may not be, since denial and concealment of alcohol intake are common.

Clinical assessment
The patient should be asked to describe a typical week’s drinking, quantified in terms of units of alcohol (1 unit contains approximately 8 g alcohol and is the equivalent of half a pint of beer, a single measure of spirits or a small glass of wine). The history from the patient may need corroboration by the general practitioner (GP), earlier medical records and family members.
Hallucinations
Hallucinations are defined as sensory perceptions occurring without external stimuli. They can occur in any sensory modality but most commonly are visual or auditory. Typical examples are hearing voices when no one else is present, or seeing ‘visions’. Hallucinations have the quality of ordinary perceptions and are perceived as originating in the external world, not in the patient’s own mind (when they are termed ‘pseudo-hallucinations’). Those occurring when falling asleep (‘hypnagogic’) and on waking (‘hypnopompic’) are a normal phenomenon and not pathological. Hallucinations should be distinguished from illusions, which are misperceptions of real external stimuli (such as mistaking a shrub for a person in poor light).

Clinical assessment
Careful and tactful enquiry is required because agitation, terror or the fear of being thought ‘mad’ may make patients unable or unwilling to volunteer or describe their abnormal beliefs or perceptions. The nature of hallucinations can be important diagnostically; for example, ‘running commentary’ voices that discuss the patient are strongly associated with schizophrenia. In general, auditory hallucinations suggest schizophrenia, while hallucinations in other sensory modalities, especially vision but also taste and smell, suggest an organic cause, such as substance misuse, delirium or temporal lobe epilepsy.

Hallucinations and delusions often co-occur. If their content is consistent with coexisting emotional symptoms, they are described as ‘mood-congruent’. Thus, patients with severely depressed mood may believe themselves responsible for all the evils in the world, and hear voices saying, “You are worthless. Go and kill yourself.” In this case, the diagnosis of depressive psychosis is made on the basis of the congruence of different phenomena (mood, delusion and hallucination). Incongruence between hallucinations, delusions and mood suggests schizophrenia.

Investigations
The presence of hallucinations and/or delusions should not automatically trigger a round of expensive investigations; rather, careful clinical assessment of the nature, extent and time course of the patient’s symptoms will generate a list of likely diagnoses, and investigations can then be intelligently deployed to differentiate between these. When hallucinations and/or delusions arise in the context of disturbed consciousness and impaired cognition, the diagnosis is usually an organic disorder, most commonly delirium and/or dementia, and should be investigated accordingly.

Management
The management of hallucinations and/or delusions is primarily the management of the underlying condition (such as delirium, schizophrenia, mania or psychotic depression). Certain principles apply, however, whatever the underlying cause.

Hallucinations and delusions can be very real to, and often frightening for, the person who is experiencing them. Patients will often seek reassurance from the doctor. The doctor should acknowledge that these experiences are real for the patient while avoiding being drawn into colluding with the patient’s false beliefs or perceptions. Statements such as ‘Sometimes when we are unwell our brain plays tricks on us’ can help to reassure a patient. Where the patient lacks insight, however, a more neutral ‘We will have to agree to disagree’ may be necessary to avoid conflict.

Antipsychotic medication can reduce psychotic symptoms, such as hallucinations and delusion, and is often used in combination with other sedating medication (such as a benzodiazepine) to alleviate acute distress and reduce behavioural disturbance.

Low mood
It is not uncommon for general hospital patients to report low mood. It is important to differentiate an understandable, self-limiting reaction to adversity (such as physical illness or bad news), which is normal and requires support rather than ‘treatment’, from a depressive disorder, which is characterised by a more severe and persistent disturbance of mood and requires specific treatment.

Clinical assessment
Depression is a relatively common illness, with a prevalence of approximately 5% in the general population and 10%–20% in medical patients. It is important to note that depression has physical as well as mental symptoms (Box 31.8). The diagnosis of depression in the medically ill, who may have physical symptoms of disease such as weight loss, fatigue, disturbed sleep, reduced appetite and so on that overlap with the physical symptoms of depression, relies on detection of the core psychological symptoms of ‘anhedonia’ (inability to experience pleasure) and the negative cognitive triad (see Box 31.18).

In some cases, depression may occur as a result of a direct effect of a medical condition or its treatment on the brain, when it is referred to as an ‘organic mood disorder’ (Box 31.9).

Investigations
When a patient appears to be low in mood, it is good practice to ask them specifically about their mood. Do they feel low (nausea, over-sedation, parkinsonism and so on can all cause a patient to appear low in mood). If so, how long have they been feeling low? Are they still able to enjoy things? To what do they attribute their low mood? If the low mood is persistent, not adequately explained by circumstances and/or associated with anhedonia, the patient should be investigated for depression. Where a patient’s mood is extremely low, the clinician should ask about suicide. Asking about suicide does not increase the risk of it occurring, whereas failure to enquire denies the opportunity to prevent it. The assessment of suicide risk is described in the self-harm section later in this chapter.
Management
Where a patient’s low mood is an understandable reaction to adversity, the clinical team can support the patient by minimising uncertainty through open and effective clinical communication and by addressing isolation (allowing access to visitors, telephone and so on). More details of the strategies available for management of depression are provided later in this chapter.

Elevated mood
Elevated mood is much less common than depressed mood, and in medical settings is often secondary to drug or alcohol misuse, an organic disorder or medical treatment. Where none of these applies, the patient may be experiencing a manic (or, if less severe, “hypomanic”) episode as part of a bipolar affective disorder. Mania is the converse of depression. It may manifest as infectious joviality, over-activity, lack of sleep and appetite, undue optimism, over-talkativeness, irritability, and recklessness in spending and sexual behaviour. When elated mood is severe, psychotic symptoms are often evident, like delusions of grandeur such as believing erroneously that one is royalty.

Investigations
The first investigation for any medical patient presenting with persistent and inexplicable elevated mood in the absence of a history of bipolar affective disorder is a medication review. Mania is a relatively common side-effect of certain classes of drug, such as glucocorticoids, and is a rare side-effect of many other drugs. Recreational, herbal and over-the-counter preparations should also be considered. Second-line investigations include tests for Cushing’s disease, thyrotoxicosis, syphilis and encephalitis.

Management
The management of bipolar disorder and disturbed or aggressive behaviour are discussed in the relevant sections later in this chapter. The management of organic mania involves identifying and addressing the underlying cause.

Anxiety
Anxiety may be transient, persistent, episodic or limited to specific situations. The symptoms of anxiety are both psychological and physical (Box 31.10). The differential diagnosis of anxiety is shown in Box 31.11. Most anxiety is part of a transient adjustment to stressful events: adjustment disorders. Other more persistent forms of anxiety are described in detail on page 1254.

Investigations
Anxiety may occasionally be a manifestation of a medical condition such as thyrotoxicosis (see Box 31.11). Tests to exclude or confirm these conditions should be considered, particularly if anxiety is a new symptom that has arisen in the absence of an obvious stressor.

31.10 Symptoms of anxiety disorder

<table>

<td>Breathlessness</td>
</tr>
<tr>
<td></td>
<td>Headache</td>
</tr>
</tbody>
</table>

31.11 Differential diagnosis of anxiety

- Normal response to threat
- Adjustment disorder
- Generalised anxiety disorder
- Panic disorder
- Phobic disorder
- Organic (medical) cause:
  - Hyperthyroidism
  - Paroxysmal arrhythmias
  - Phaeochromocytoma
  - Alcohol and benzodiazepine withdrawal
  - Hypoglycaemia
  - Temporal lobe epilepsy

Management
The management of specific anxiety disorders is discussed later in this chapter. Benzodiazepines and related drugs, while extremely effective in the short term, cause tolerance and unpleasant or even dangerous withdrawal syndromes if used for more than a few weeks.

Psychological factors affecting medical conditions

Psychological factors may influence the presentation, management and outcome of medical conditions. Specific factors are shown in Box 31.12. The most common psychiatric diagnoses in the medically ill are anxiety and depressive disorders. Often these appear understandable as adjustments to illness and its treatment; however, if the anxiety and depression are severe and persistent, they may complicate the management of the medical condition and active management is required. Anxiety may present as an increase in somatic symptoms, such as breathlessness, tremor or palpitations, or as the avoidance of medical treatment. It is most common in those facing difficult or painful treatments, deterioration of their illness or death. Depression may manifest as increased physical symptoms, such as pain, fatigue and disability, as well as with depressed mood and loss of interest and pleasure. It is most common in patients who have suffered actual or anticipated losses, such as receiving a terminal diagnosis or undergoing disfiguring surgery.

Treatment is by psychological and/or pharmacological therapies, as described later in this chapter in the section on depression. Care is required when prescribing psychotropic drugs to the medically ill in order to avoid exacerbation of the medical condition and harmful interactions with other prescribed drugs.

Medically unexplained somatic symptoms

Medically unexplained somatic symptoms (MUS) is the term used to describe the situation where patients have symptoms that cannot be explained on the basis of a physical disorder (see Fig. 31.6). They fall into characteristics patterns (Box 31.13), and are very common in patients
attending general medical outpatient clinics. Almost any symptom can be medically unexplained, including:

- pain (including back, chest, abdominal, pelvic and headache)
- fatigue
- fits, ‘funny turns’, dizziness and feelings of weakness.

Patients with MUS may receive a medical diagnosis of a so-called ‘functional somatic syndrome’, such as irritable bowel syndrome (Box 31.13), and may also merit a psychiatric diagnosis on the basis of the same symptoms. The most frequent psychiatric diagnoses associated with MUS are anxiety or depressive disorders. When these are absent, a diagnosis of somatof orm disorder may be appropriate. Somatof orm disorders are discussed in more detail later in this chapter.

### Self-harm

Self-harm (SH) is a common reason for presentation to medical services. The term ‘attempted suicide’ is potentially misleading, as most of these patients are not trying to kill themselves. Most cases of SH involve overdose, of either prescribed or non-prescribed drugs (Ch. 10). Less common methods include asphyxiation, drowning, hanging, jumping from a height or in front of a moving vehicle, and the use of firearms. Methods that carry a high chance of being fatal are more likely to be associated with serious psychiatric disorder. Self-cutting is common and often repetitive, but rarely leads to contact with medical services.

The incidence of SH varies over time and between countries. In the UK, the lifetime prevalence of suicidal ideation is 15% and that of acts of SH is 4%–5%. SH is more common in women than men, and in young rather than older adults. (In contrast, completed suicide is more common in men and older people; Box 31.14.) There is a higher incidence of SH among lower socioeconomic groups, particularly those living in crowded, socially deprived urban areas. There is also an association with alcohol misuse, child abuse, unemployment and recent relationship problems.

#### Clinical assessment

The main differential diagnosis is from accidental poisoning and so-called ‘recreational’ overdose in drug users. It must be remembered that SH is not a diagnosis but a presentation, and may be associated with any psychiatric diagnosis, the most common being adjustment disorder, substance and alcohol misuse, depressive disorder and personality disorder. In many cases, however, no psychiatric diagnosis can be made.
Patient admitted following deliberate self-harm

Medical assessment to determine need for urgent medical treatment

Urgent medical treatment needed?

No

Yes

Medical treatment

Psychiatric assessment

Immediate and significant suicide risk

No

Yes

Plan to minimise risk:
- remove methods of self-harm
- arrange for special support
- consider use of mental health legislation

Assess for significant psychiatric illness Suspected?

No

Yes

Assess and arrange management for other problems

Consider:
- psychiatric admission (using mental health legislation if necessary)
- referral to psychiatric service for outpatient treatment

Disturbed behaviour

Does it seem likely to be caused by mental disorder?

Yes

No

Consider calling security/police

Is the behaviour putting the patient or others at risk?

Yes

No

Monitor and review

Are measures effective?

1. Ensure availability of adequate personnel to provide ‘overwhelming force’
2. Try to attain a safe and quiet environment
3. Consider emergency sedation with haloperidol (0.5–5 mg IM/orally)
   and/or benzodiazepine (diazepam 5–10 mg IV slowly in view of risk of respiratory depression or lorazepam 1–2 mg IM/orally)

Consult with senior staff
Consider repeating drug, increasing dose or using other agents such as midazolam or paraldehyde

Fig. 31.3 Acute management of disturbed behaviour. (IM = intramuscular; IV = intravenous)

31.15 Assessment of patients after self-harm

Current attempt

- Patient’s account
- Degree of intent at the time: preparations, plans, precautions against discovery, note
- Method used, particularly whether violent
- Degree of intent now
- Symptoms of psychiatric illness

Background

- Previous attempts and their outcome
- Family and personal history
- Social support
- Previous response to stress
- Extent of drug and alcohol misuse

31.16 Psychiatric emergencies

- Intervene as necessary to reduce the risk of harm to the patient and to others
- Adopt a calm, non-threatening approach
- Arrange availability of other staff and parental medication
- Consider diagnostic possibilities of drug intoxication, acute psychosis and delirium
- Involve friends and relatives as appropriate

An attempt should be made to try to identify the factors that are contributing to the disturbed behaviour. When the patient is cooperative, these factors are best determined at interview. Other sources of information about the patient include medical and psychiatric records, and discussion with nursing staff, family members and other informants, including the patient’s GP. The following information should be sought:

- psychiatric, medical (especially neurological) and criminal history
- current psychiatric and medical treatment
• alcohol and drug misuse
• recent stressors
• the time course and accompaniments of the current episode in terms of mood, belief and behaviour.

Observation of the patient’s behaviour may also yield useful clues. Do they appear to be responding to hallucinations? Are they alert or variably drowsy and confused? Are there physical features suggestive of drug or alcohol misuse or withdrawal? Are there new injuries or old scars, especially on the head? Do they smell of alcohol or solvents? Do they bear the marks of drug injection? Are they unwashed and unkempt, suggesting a gradual development of their condition?

Investigations
Depending on the results of clinical assessment, routine biochemistry, haematology and analysis of blood or urine for illicit drugs or alcohol may be required.

Management
Measures such as restraint and sedation may be required in patients with acute behavioural disturbance in order to identify the cause and to protect the patient and other people from harm. While this potentially raises legal issues, in most countries, including the UK, common law confers on doctors the right, and indeed the duty, to intervene against a patient’s wishes if this is necessary. Sedation may be required and can be achieved with antipsychotic drugs (such as haloperidol) and/or benzodiazepines (such as lorazepam or diazepam). The choice of drug, dose, route and rate of administration depends on the patient’s age, gender and physical health, as well as the likely cause of the disturbed behaviour. The benefits of sedation must always be balanced against the potential risks. When prescribing benzodiazepines, consider the risk of respiratory depression (particularly in patients with lung disease) and encephalopathy (in those with liver disease). When prescribing antipsychotic drugs for acute sedation, consider the risk of acute dystonias (such as ‘oculogyric crisis’) and acute arrhythmias (in patients with heart disease). Thus for a frail older woman with emphysema and delirium, sedation may be achieved with a low dose (0.5mg) of oral haloperidol, while for a strong young man with an acute psychotic episode, 10mg or more of intravenous diazepam and a similar dose of haloperidol may be required. A parenterally administered anticholinergic agent, such as procyclidine, should be available to treat extrapyramidal effects from haloperidol if they arise. Flumazenil can be used to reverse respiratory depression caused by benzodiazepines.

If the initial assessment suggests that the patient has an acute psychiatric disorder, then admission to a psychiatric facility may be indicated. If a medical cause is more likely, psychiatric transfer is usually inappropriate and the patient should be managed in a medical setting, with whatever nursing and security support is required. Where it is clear that there is no medical or psychiatric illness, the person should be removed from the hospital, to police custody if necessary.

Many countries, such as the UK, also have specific mental health legislation that may be used to detain patients if necessary.

Principles of management
The multifactorial origin of most psychiatric disorders means that there are multiple potential targets for treatment. It is useful to consider management strategies within a bio-psycho-social framework. This can help to address the biological factors that contribute to the illness with medication and other physical treatments such as electroconvulsive therapy, while also considering the potential role for psychological therapies and changes to the patient’s social environment.

Pharmacological treatments
These aim to relieve psychiatric disorder by modifying brain function. The main biological treatments are psychotropic drugs. These are widely used for various purposes; a pragmatic classification is set out in Box 31.17. It should be noted that some drugs have applications to more than one condition; for example, antidepressants are also widely used in the treatment of anxiety and chronic pain. The specific subgroups of psychotropic drugs are discussed in the sections on the appropriate disorders below.

Electroconvulsive therapy
Electroconvulsive therapy (ECT) entails producing a convulsion by the brief administration of a high-voltage direct-current impulse to the head while the patient is anaesthetised and paralysed by muscle relaxant. If properly administered, it is remarkably safe, has few side-effects and is of proven efficacy for severe depressive illness. There may be headaches and amnesia for events occurring a few hours before ECT (retrograde) and after it (anterograde). Pronounced amnesia can occur but is infrequent and difficult to distinguish from the effects of severe depression.

Other forms of electromagnetic stimulation
Clinical trials of transcranial magnetic stimulation (TMS) and vagal nerve stimulation (VNS) suggest they may have a limited role in patients with depression refractory to conventional treatments.

Surgery
Surgery to the brain (psychosurgery) has a very limited place and then only in the treatment of severe chronic psychiatric illness resistant to other measures. Frontal lobotomies are never done now, and pre-frontal leucotomies are very rare. Operations these days usually target specific sub-regions and tracts of the brain.

*Figure 31.7* Classification of commonly used psychotropic drugs.
Psychological therapies

These treatments are useful in many psychiatric disorders and also in non-psychiatric conditions. They are based on talking with patients, either individually or in groups. Sometimes discussion is supplemented by ‘homework’ or tasks to complete between treatment sessions. Psychological treatments take a number of forms based on the duration and frequency of contact, the specific techniques applied and their underlying theory.

General supportive psychotherapy

General psychotherapy should be part of all medical treatment. It involves empathic listening to the patient’s account of their symptoms and associated fears and concerns, followed by the sympathetic provision of accurate information that addresses these.

Cognitive therapy

This therapy is based on the observation that some psychiatric disorders are associated with systematic errors in the patient’s conscious thinking, such as a tendency to interpret events in a negative way or see them as unduly threatening. A triad of ‘cognitive errors’ has been described in depression (Box 31.18). Cognitive therapy aims to help patients to identify such cognitive errors and to learn how to challenge them. It is widely used for depression, anxiety, and eating and somatoform disorders, and also increasingly in psychoses.

Behaviour therapy

This is a practically orientated form of treatment, in which patients are assisted in changing unhelpful behaviour, such as helping patients to implement carefully graded exposure to the feared stimulus in phobias.

Cognitive behaviour therapy

Cognitive behaviour therapy (CBT) combines the methods of behaviour therapy and cognitive therapy. It is the most widely available and extensively researched psychological treatment.

Problem-solving therapy

This is a simplified brief form of CBT, which helps patients actively tackle problems in a structured way (Box 31.19). It can be delivered by non-psychiatric doctors and nurses after appropriate training and is commonly used to help patients who self-harm in response to a situational crisis.

Psychodynamic psychotherapy

This treatment, also known as ‘interpretive psychotherapy’, was pioneered by Freud, Jung and Klein, among others. It is based on the theory that early life experience generates powerful but unconscious motivations. Psychotherapy aims to help the patient to become aware of these unconscious factors on the assumption that, once identified, their negative effects are reduced. The relationship between therapist and patient is used as a therapeutic tool to identify issues in patients’ relationships with others, particularly parents, which may be replicated or transferred to their relationship with the therapist. Explicit discussion of this relationship is the basis for the treatment, which traditionally requires frequent sessions over a period of months or even years.

Interpersonal psychotherapy

Interpersonal psychotherapy (IPT) is a specific form of brief psychotherapy that focuses on patients’ current interpersonal relationships and is an effective treatment for mild to moderate depression.

Social interventions

Some adverse social factors, such as unemployment, may not be readily amenable to intervention but others, such as access to benefits and poor housing, may be. Patients can be helped to address these problems themselves by being taught problem-solving. Befrienders and day centres can reduce social isolation, benefits advisers can ensure appropriate financial assistance, and medical recommendations can be made to local housing departments to help patients obtain more appropriate accommodation.

Psychiatric disorders

Dementia

Dementia is a clinical syndrome characterised by a loss of previously acquired intellectual function in the absence of impaired arousal. It affects 5% of those over 65 and 20% of those over 85. It is defined as a global impairment of cognitive function and is typically progressive and non-reversible. There are many subtypes (Box 31.20) but Alzheimer’s disease and diffuse vascular dementia are the most common. Rarer causes of dementia should be actively sought in younger patients and those with short histories.

Pathogenesis

Dementia may be divided into ‘cortical’ and ‘subcortical’ types, depending on the clinical features.

Clinical features

The usual presentation is with a disturbance of personality or memory dysfunction. A careful history is essential and it is important to interview both the patient and a close family member. Simple bedside tests, such as the MoCA, are useful in assessing the nature and severity of the cognitive deficit, although a more intensive neuropsychological assessment may sometimes be required, especially if there is diagnostic uncertainty. It is important to exclude a focal brain lesion. This is done by determining that there is cognitive disturbance in more than one area. Mental state assessment is important to seek evidence of depression, which may coexist with or occasionally cause apparent cognitive impairment. Many of the primary degenerative diseases that cause dementia have characteristic features that may allow a specific diagnosis during life. Creutzfeldt–Jakob disease, for example, is usually quickly progressive (over months) and is associated with myoclonus. The more slowly progressive dementias are more difficult to distinguish during life, but

</table>

Fronto-temporal dementia typically presents with signs of temporal or frontal lobe dysfunction, whereas Lewy body dementia may present with visual hallucinations. The course may also help to distinguish types of dementia. Gradual worsening suggests Alzheimer’s disease, whereas stepwise deterioration is typical of vascular dementia.

**Investigations**

The aim is to seek treatable causes and to estimate prognosis. This is done using a standard set of investigations (Box 31.21). Imaging of the brain can exclude potentially treatable structural lesions, such as hydrocephalus, cerebral tumour or chronic subdural haematoma, though the only abnormality usually seen is that of generalised atrophy. An electroencephalogram (EEG) may be helpful if Creutzfeldt–Jakob disease is suspected, as characteristic abnormalities of generalised periodic sharp wave pattern are usually observed. If the initial tests are negative, more invasive investigations, such as lumbar puncture or, very rarely, brain biopsy, may be indicated.

**Management**

This is mainly directed at addressing treatable causes and providing support for patients and carers. Tackling risk factors may slow deterioration, such as by management of hypertension in vascular dementia, or abstinence and vitamin replacement in toxic/nutritional dementias. Psychotropic drugs may have a role in alleviating symptoms, such as disturbance of sleep, perception or mood, but should be used with care because of an increased mortality in patients who have been treated long-term with these agents. Sedation is not a substitute for good care of patients and carers or, in the later stages, attentive residential nursing care. In the UK, incapacity and mental health legislation may be required to manage patients’ financial and domestic affairs, as well as to determine their safe placement. If the diagnosis is Alzheimer-type dementia, cholinesterase inhibitors and memantine may slow progression for a time.

### Alzheimer’s disease

Alzheimer’s disease is the most common form of dementia. It increases in prevalence with age and is rare in people under 45 years.

### 31.21 Initial investigation of dementia

**In most patients**

- Imaging of head (CT and/or MRI)
- Blood tests:
  - Full blood count, erythrocyte sedimentation rate
  - Urea and electrolytes, glucose
  - Calcium, liver function tests
  - Thyroid function tests
  - Vitamin B12
  - Syphilis serology
  - ANA, anti-dsDNA
- Chest X-ray
- Electroencephalography

**In selected patients**

- Lumbar puncture
- HIV serology
- Brain biopsy

(ANA = antinuclear antibody; anti-dsDNA = anti-double-stranded DNA; CT = computed tomography; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging)

**Pathogenesis**

Genetic factors play an important role and about 15% of cases are familial. These cases fall into two main groups: early-onset disease with autosomal dominant inheritance and a later-onset group where the inheritance is polygenic. Mutations in several genes have been described but most are rare and/or of small effect. The inheritance of one of the alleles of apolipoprotein ε (apo ε4) is associated with an increased risk of developing the disease (2–4 times higher in heterozygotes and 6–8 times higher in homozygotes). Its presence is, however, neither necessary nor sufficient for the development of the disease and so genetic testing for ApoE4 is not clinically useful. The brain in Alzheimer’s disease is macroscopically atrophic, particularly the cerebral cortex and hippocampus. Histologically, the disease is characterised by the presence of senile plaques and neurofibrillary tangles in the cerebral cortex. Histological
staining demonstrates significant quantities of amyloid in the plaques (Fig. 31.4); these typically stain positive for the protein ubiquitin, which normally is involved in targeting unwanted or damaged proteins for degradation. This has led to the suggestion that the disease may be due to defects in the ability of neuronal cells to degrade unwanted proteins. Many different neurotransmitter abnormalities have also been described. In particular, there is impairment of cholinergic transmission, although abnormalities of noradrenaline (norepinephrine), 5-HT, glutamate and substance P have also been described.

**Clinical features**

The key clinical feature is impairment of the ability to remember new information. Hence, patients present with gradual impairment of memory, usually in association with disorders of other cortical functions. Short- and long-term memory are both affected but defects in the former are usually more obvious. Later in the course of the disease, typical features include apraxia, visuospatial impairment and aphasia. In the early stages of the disease patients may notice these problems, but as the disease progresses it is common for patients to deny that there is anything wrong (anosognosia). In this situation, patients are often brought to medical attention by their carers. Depression is commonly present. Occasionally, patients become aggressive, and the clinical features can be made acutely worse by intercurrent physical disease.

Patients typically present with subjective memory loss, sometimes getting lost in familiar locations. A history of progressive memory loss and associated functional impairment, corroborated by an informant, is the key to making the diagnosis. Cognitive testing and neuroimaging can be helpful but in themselves are not diagnostic.

**Investigations**

Investigation is aimed at excluding treatable causes of dementia (see Box 31.20), as histological confirmation of the diagnosis usually occurs only after death.

---

**Fig. 31.5 Fronto-temporal dementia.** 
A. Lateral view of formalin-fixed brain from a patient who died of Pick’s disease, showing gyral atrophy of frontal and parietal lobes and a more severe degree of atrophy affecting the anterior half of the temporal lobe (arrow). 
B. High power (x200) view of hippocampal pyramidal layer, prepared with monoclonal anti-tau antibody. Many neuronal cell bodies contain sharply circumscribed, spherical cytoplasmic inclusion bodies (Pick bodies, arrows).  
(A and B) Courtesy of Dr J. Xuereb.

**Management**

Treatment with anticholinesterases, such as donepezil, rivastigmine and galantamine, has been shown to be of some benefit at slowing progression of cognitive impairment in the early stages of the disease while post-synaptic cholinergic receptors are still available. The N-methyl-D-aspartate (NMDA) receptor antagonist memantine slightly enhances learning and memory in early disease and can also be useful in selected patients with more advanced disease. Novel treatments are under development to block amyloid plaque formation directly, by inhibiting the enzyme γ-secretase. Non-pharmacological approaches include the provision of a familiar environment for the patient and support for the carers. Many patients are anxious or depressed, and if this is confirmed, treatment with antidepressant medication may be helpful.

---

**Fronto-temporal dementia**

Fronto-temporal dementia encompasses a number of different syndromes characterised by behaviour abnormalities and impairment of language. Symptoms usually occur before the age of 60 and the prevalence has been estimated at 15 per 100,000 in the population aged between 45 and 65 years. The three major clinical subtypes are behavioural-variant fronto-temporal dementia, primary progressive aphasia and semantic dementia. Pick’s disease is a common cause of the first two in particular. Genetic factors play an important role and familial cases have been described caused by mutations in several genes, including MAPT, which encodes microtubule-associated protein tau, GRN, TDP43, FUS, VCP and C9orf72. The causal mutations trigger abnormal accumulation of tau and other proteins in brain tissue, which are seen as cytoplasmic inclusion bodies on histological examination (Fig. 31.5). It is of interest that some gene mutations that cause fronto-temporal dementia, such as VCP, are also associated with amyotrophic lateral sclerosis, inclusion body myopathy and Paget’s disease of bone, suggesting that these disorders
share a similar pathogenic basis in which cellular degeneration is caused by accumulation of abnormal proteins. The clinical presentation may be with personality change due to frontal lobe involvement or with language disturbance due to temporal lobe involvement. In contrast to Alzheimer’s disease, memory is relatively preserved in the early stages. There is no specific treatment. Disinhibition and compulsive behaviours can be helped by selective serotonin re-uptake inhibitors (SSRIs). Although fronto-temporal dementia shares certain symptoms with Alzheimer’s, it cannot be treated with anticholinesterases because cholinergic systems are not affected.

### Lewy body dementia

This neurodegenerative disorder is clinically characterised by dementia and signs of Parkinson’s disease. It is often inherited and mutations in the α-synuclein and β-synuclein genes have been identified in affected patients. These mutations result in accumulation of abnormal protein aggregates in neurons that contain the protein α-synuclein in association with other proteins, including ubiquitin (see Fig. 28.30). The cognitive state often fluctuates and there is a high incidence of visual hallucinations. Affected individuals are particularly sensitive to the side-effects of anti-Parkinsonian medication and also to antipsychotic drugs. There is no curative treatment but anticholinesterase drugs can be helpful in slowing progression of cognitive impairment.

### Alcohol misuse and dependence

Alcohol consumption associated with social, psychological and physical problems constitutes misuse. The criteria for alcohol dependence, a more restricted term, are shown in Box 31.22. Approximately one-quarter of male patients in general hospital medical wards in the UK have a current or previous alcohol problem.

**Pathogenesis**

Availability of alcohol and social patterns of use appear to be the most important factors. Genetic factors predispose to dependence. The majority of people who misuse alcohol do not have an associated psychiatric disorder, but a few drink heavily in an attempt to relieve anxiety or depression.

**Clinical features**

The modes of presentation of alcohol misuse and complications are summarised below.

**Social problems**

Common features include absenteeism from work, unemployment, marital tensions, child abuse, financial difficulties and problems with the law, such as violence and traffic offences.

**Low mood**

Low mood is common since alcohol has a direct depressant effect and heavy drinking creates numerous social problems. Attempted and completed suicide are associated with alcohol misuse.

**Anxiety**

People who are anxious may use alcohol as a means of relieving anxiety in the short term and this can develop into dependence. Conversely, alcohol withdrawal increases anxiety.

### Alcohol withdrawal syndrome

The features are described in Box 31.23. Symptoms usually become maximal about 2–3 days after the last drink and can include seizures. The term ‘delirium tremens’ is used to describe severe alcohol withdrawal syndrome characterised by both delirium (characteristically, agitation and visual hallucinations) and physiological hyper-arousal (tremor, sweating and tachycardia). It has a significant mortality and morbidity (see Box 31.23).

**Hallucinations**

Hallucinations (characteristically visual but sometimes in other modalities) are common in delirium tremens. Less common is the phenomenon called ‘alcoholic hallucinosis’, where a patient with alcohol dependence experiences auditory hallucination in clear consciousness at a time when they are not withdrawing from alcohol.

**Wernicke–Korsakoff syndrome**

This is a rare but important indirect complication of chronic alcohol misuse. It is an organic brain disorder resulting from damage to the mamillary bodies, dorsomedial nuclei of the thalamus and adjacent areas of periventricular grey matter caused by a deficiency of thiamin (vitamin B₁₂). The syndrome most commonly results from long-standing heavy drinking and an inadequate diet but can also arise from malabsorption or even protracted vomiting. Wernicke’s encephalopathy (rystagnus or ophthal-moplegia with ataxia and delirium) often presents acutely and, without prompt treatment (see below), can progress and become irreversible. Korsakoff syndrome (severe short-term memory deficits and confabulation) can develop chronically or acutely (with Wernicke’s).

**Alcohol-related brain damage**

The term alcohol-related brain damage (ARBD) is often used as a collective description of the many brain pathologies associated with alcohol excess.
which often coexist in the same patient. Acute alcohol intoxication causes ataxia, slurred speech, emotional incontinence and aggression. Very heavy drinkers may experience periods of amnesia for events that occurred during bouts of intoxication, termed ‘alcoholic blackouts’. Established alcohol dependence may lead to ‘alcoholic dementia’, a global cognitive impairment resembling Alzheimer’s disease, but which does not progress and may even improve if the patient becomes abstinent. Heavy alcohol use can damage the brain indirectly through Wernicke–Korsakoff syndrome (see above), head injury, hypoglycaemia and encephalopathy.

Effects on other organs
These are protean and virtually any organ can be involved (see Box 31.23). These effects are discussed in detail in other chapters in this book.

Diagnosis
The diagnosis of alcohol excess may emerge while taking the patient’s history, but many patients do not tell the truth about their alcohol intake. Alcohol misuse may also present through its effects on one or more aspects of the patient’s life, as listed above. Alcohol dependence commonly presents with withdrawal in those admitted to hospital, as they can no longer maintain their high alcohol intake in this setting.

Management
For the person misusing alcohol, provision of clear information from a doctor about the harmful effects of alcohol and safe levels of consumption is often all that is needed. In more serious cases, patients may have to be advised to alter leisure activities or change jobs to help them to reduce their consumption. Psychological treatment is used for people who have recurrent relapses and is usually available at specialised centres. Support to stop drinking is also provided by voluntary organisations, such as Alcoholics Anonymous (AA) in the UK.

Alcohol withdrawal syndromes can be prevented, or treated once established, with long-acting benzodiazepines. Large doses may be required (such as diazepam 20 mg 4 times daily), tailed off over a period of 5-7 days as symptoms subside. Prevention of the Wernicke–Korsakoff syndrome requires the immediate use of high doses of thiamin, which is initially given parenterally in the form of Pabrinex (two vials 3 times daily for 48 hrs, longer if symptoms persist) and then orally (100 mg 3 times daily). There is no treatment for Wernicke–Korsakoff syndrome once it has arisen. The risk of side-effects, such as respiratory depression with benzodiazepines and anaphylaxis with Pabrinex, is small when weighed against the potential benefits of treatment.

Acamprosate (665 mg 3 times daily) may help to maintain abstinence by reducing the craving for alcohol. Disulfiram (200-400 mg daily) can be given as a deterrent to patients who have difficulty resisting the impulse to drink after becoming abstinent. It blocks the metabolism of alcohol, causing acetaldehyde to accumulate. When alcohol is consumed, an unpleasant reaction follows, with headache, flushing and nausea. Disulfiram is always an adjunct to other treatments, especially supportive psychotherapy. Treatment with antidepressants may be required if depression is severe or does not resolve with abstinence. Antipsychotics, such as chlorpromazine (100 mg 3 times daily), are needed for alcoholic hallucinosis. Although such treatment may be successful, there is a high relapse rate.

Prognosis
Between 80% and 90% of patients with established alcohol dependence syndrome who embark on medically supervised detoxification will successfully complete detoxification without encountering significant complications. Sustaining abstinence is more challenging than achieving it; however. Studies indicate that 1 year after successful detoxification, only 20% of patients will remain abstinent. This figure rises to approximately 30% for patients who are engaged with alcohol services, and to over 40% if such specialist support is combined with supervised disulfiram treatment.

Substance misuse disorder

Dependence on and misuse of both illegal and prescribed drugs is a major problem worldwide. Drugs of misuse are described in detail in Chapter 7. They can be grouped as follows.

Sedatives
These commonly give rise to physical dependence, the manifestations of which are tolerance and a withdrawal syndrome. Drugs include benzodiazepines, opiates (including morphine, heroin, methadone and dicyclomine) and barbiturates (now rarely prescribed). Overdosage with sedatives can be fatal, primarily as a result of respiratory depression (Ch. 10). Withdrawal from opiates is notoriously unpleasant, and withdrawal from benzodiazepines and barbiturates can cause prolonged anxiety and even hallucinations and/or seizures.

Intravenous opiate users are prone to bacterial infections, hepatitis B, hepatitis C and HIV infection through needle contamination. Accidental overdose is common, mainly because of the varied and uncertain potency of illicit supplies of the drug. The withdrawal syndrome, which can start within 12 hours of last use, presents with intense craving, rhinorhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Stimulants
Stimulant drugs include amphetamines and cocaine. They are less dangerous than the sedatives in overdose, although they can cause cardiac and cerebrovascular problems through their pressor effects. Physical dependence syndromes do not arise, but withdrawal causes a rebound lowering in mood and can give rise to an intense craving for further use, especially in any form of drug with a rapid onset and offset of effect, such as crack cocaine. Chronic ingestion can cause a paranoid psychosis similar to schizophrenia. A ‘toxic psychosis’ (delirium) can occur with high levels of consumption. Unpleasant tactile hallucinations described as ‘like ants crawling under the skin’ (formication) may be prominent in either acute intoxication or withdrawal.

Hallucinogens
The hallucinogens are a disparate group of drugs that cause prominent sensory disturbances. They include cannabis, ecstasy, lysergic acid diethylamide (LSD), Psilocybin (magic mushrooms) and a variety of synthetic cannabinoids (as one of the so-called ‘legal highs’ or ‘novel psychoactive substances’). A toxic confusional state can occur after heavy cannabis consumption. Acute psychotic episodes are well recognised, especially in those with a family or personal history of psychosis, and there is evidence that prolonged heavy use increases the risk of developing schizophrenia. Paranoic psychoses have been reported in association with ecstasy. A chronic psychosis has also been documented after regular LSD use.

Organic solvents
Solvent inhalation (glue sniffing) is popular in some adolescent groups. Solvents produce acute intoxication characterised by euphoria, excitement, dizziness and a floating sensation. Further inhalation leads to loss of consciousness; death can occur from the direct toxic effect of the solvent, or from asphyxiation if the substance is inhaled from a plastic bag.

Pathogenesis
Many of the causal factors for alcohol misuse also apply to substance misuse. The main factors are the psychological and behavioural vulnerabilities described above, cultural pressures, particularly within a peer group, and availability of a drug. In the case of some drugs such as opiates, medical over-prescribing has increased their availability, but there has also been a relative decline in the price of illegal drugs. Most drug users take a range of drugs; this is termed ‘poly-drug misuse’.
Diagnosis

As with alcohol, the diagnosis either may be apparent from the history and examination, or may be made only once the patient presents with a complication. Drug screening of samples of urine or blood can be valuable in confirming the diagnosis, especially if the patient persists in denial.

Management

The first step is to determine whether patients wish to stop using the drug. If they do not, they can still benefit from advice about how to minimise harm from their habit, such as how to obtain and use clean needles for those who inject. For those who are physically dependent on sedative drugs, substitute prescribing (using methadone, for example, in opiate dependence) may help stabilise their lives sufficiently to allow a gradual reduction in dosage until they reach abstinence. Some specialist units offer inpatient detoxification. The medical management of overdose is discussed in Chapter 10. The drug lofexidine, a centrally acting α-agonist, can be useful in treating the autonomic symptoms of opiate withdrawal, as can clonidine, although this carries a risk of hypotension and is best used by specialists. Long-acting opiate antagonists, such as naltrexone, may also have a place, again in specialist hands, in blocking the euphoriant effects of the opiate, thereby reducing addiction.

In some cases, complete opiate withdrawal is not successful and the patient functions better if maintained on regular doses of oral methadone as an outpatient. This decision to prescribe long-term methadone should be taken only by a specialist, and carried out under long-term supervision at a specialist drug treatment centre.

Substitute prescribing is neither necessary nor possible for the hallucinogens and stimulants, but the principles of management are the same as those that should accompany prescribing for the sedatives. These include identifying problems associated with the drug misuse that may serve to maintain it, and intervening where possible. Intervention may be directed at physical illness, psychiatric comorbidity, social problems or family disharmony.

Relapsing patients and those with complications should be referred to specialist drug misuse services. Support can also be provided by self-help groups and voluntary bodies, such as Narcotics Anonymous (NA) in the UK.

Schizophrenia

Schizophrenia is characterised by delusions, hallucinations and lack of insight. Acute schizophrenia may also present with disturbed behaviour, disordered thinking, or with inexcusable social withdrawal and other so-called negative symptoms and less obvious delusions and hallucinations. Schizophrenia occurs worldwide in all ethnic groups with a prevalence of about 0.5%. It is more common in men (1.4 to 1). Children of an affected parent have an approximate 10% risk of developing the illness, but this rises to 50% if an identical twin is affected. The usual age of onset is the mid-twenties but can be older, particularly in women.

Pathogenesis

There is a strong genetic contribution, usually involving many susceptibility genes, each of small effect, but 2%–3% of cases can be attributed to increased or decreased copies of genes (so-called “copy number variations”). Environmental risk factors include a history of obstetric complications at the time of the patient’s birth, childhood adversity and urban upbringing. Brain imaging techniques have identified subtle structural abnormalities in groups of people with schizophrenia, including an overall decrease in brain size (by about 3% on average), with a relatively greater reduction in temporal lobe volume (5%–10%). Episodes of acute schizophrenia may be precipitated by social stress and also by cannabis, which increases dopamine turnover. Consequently, schizophrenia is now viewed as a neurodevelopmental disorder, caused by abnormalities of brain development associated with genetic predisposition and early environmental influences, but precipitated by later triggers.

Clinical features

Acute schizophrenia should be suspected in any individual with bizarre behaviour accompanied by delusions and hallucinations that are not due to organic brain disease or substance misuse. The characteristic clinical features are listed in Box 31.24. Hallucinations are typically auditory but can occur in any sensory modality. They commonly involve voices from outside the head that talk to or about the person. Sometimes the voices repeat the person’s thoughts. Patients may also describe ‘passivity of thought’, experienced as disturbances in the normal privacy of thinking, such as the delusional belief that their thoughts are being ‘ withdrawn’ from them and perhaps ‘broadcast’ to others, and/or that alien thoughts are being “inserted” into their mind. Other characteristic symptoms are delusions of control: believing that one’s emotions, impulses or acts are controlled by others. Another phenomenon is delusional perception, a delusion that arises suddenly alongside a normal perception, such as ‘I saw the moon and I immediately knew he was evil.’ Other, less common, symptoms may occur, including thought disorder, as manifest by incomprehensible speech, and abnormalities of movement, such as those in which the patient can become immobile or adopt awkward postures for prolonged periods (catatonia).

Diagnosis

The diagnosis is made primarily on clinical grounds but investigations may be required to rule out organic brain disease. The main differential diagnosis of schizophrenia (Box 31.25) includes:

31.24 Symptoms of schizophrenia

First-rank symptoms of acute schizophrenia

- A = Auditory hallucinations – second- or third-person/écho de la pensée
- B = Broadcasting, insertion/withdrawal of thoughts
- C = Controlled feelings, impulses or acts (‘passivity’ experiences/phenomena)
- D = Delusional perception (a particular experience is bizarrely interpreted)

Symptoms of chronic schizophrenia (negative symptoms)

- Flattened (blunted) affect
- Apathy and loss of drive (avolation)
- Social isolation/withdrawal (autism)
- Poverty of speech (alogia)
- Poor self-care

31.25 Differential diagnosis of schizophrenia

</table>
• Other functional psychoses, particularly psychotic depression and mania, in which delusions and hallucinations are congruent with a marked mood disturbance (negative in depression and grandiose in mania). Schizophrenia must also be differentiated from specific delusional disorders that are not associated with the other typical features of schizophrenia.
• Organic psychoses, including delirium, in which there is impairment of consciousness and loss of orientation (not found in schizophrenia), typically with visual hallucinations.
• Drug misuse, particularly in young people.
• Auto-immune or infectious encephalitis.
• Temporal lobe epilepsy, with psychotic symptoms, in which olfactory and gustatory hallucinations may occur.

Many of those who experience acute schizophrenia go on to develop a chronic state in which the acute, so-called positive symptoms resolve, or at least do not dominate the clinical picture, leaving so-called negative symptoms that include blunt affect, apathy, social isolation, poverty of speech and poor self-care. Patients with chronic schizophrenia may also manifest positive symptoms, particularly when under stress, and it can be difficult for those who do not know the patient whether or not these are signs of an acute relapse.

Investigations
As in dementia, investigations are focused on excluding a treatable cause, such as a slow-growing brain tumour, temporal lobe epilepsy, neurosyphilis or various autoimmune conditions. These are required only in patients with neurological or other organic symptoms or signs.

Management
First-episode schizophrenia often requires admission to hospital because patients lack the insight that they are ill and are unwilling to accept treatment. In some cases, they may be at risk of harming themselves or others. Subsequent acute relapses and chronic schizophrenia are now usually managed in the community.

Drug treatment
Antipsychotic agents are effective against the positive symptoms of schizophrenia in the majority of cases. They take 2 weeks or so to be maximally effective but have some beneficial effects shortly after administration. Treatment is then ideally continued to prevent relapse. In a patient with a first episode of schizophrenia this will usually be for 1 or 2 years, but in patients with multiple episodes treatment may be required for many years. The benefits of prolonged treatment must be weighed against the adverse effects, which include extrapyramidal side-effects (EPS) like acute dystonic reactions (which may require treatment with parenteral anticholinergics), akathisia and parkinsonism. For long-term use, antipsychotic agents are often given by slow-release (depot) injections to improve adherence.

A number of antipsychotic agents are available (Box 31.26). These may be divided into first-generation drugs such as chlorpromazine and haloperidol, and second-generation drugs such as olanzapine and clozapine.

In general, the newer drugs are less likely to produce unwanted EPS but tend to cause greater weight gain and metabolic disturbances, such as dyslipidaemia. All work by blocking D₂ dopamine receptors in the brain, with the possible exception of clozapine. Clozapine can be remarkably effective in those who do not respond to other antipsychotics but can cause agranulocytosis in about 1% of patients in the first few months. Prescription therefore requires regular monitoring of white blood cell count, initially on a weekly basis, then fortnightly and monthly thereafter. Clozapine, like all antipsychotics, should not be stopped suddenly because of the likelihood of relapse. Adverse effects of antipsychotic drugs are listed in Box 31.27. Two serious adverse effects deserve special mention.

Neuroleptic malignant syndrome
This is a rare but serious condition characterized by fever, tremor and rigidity, autonomic instability and delirium. Characteristic laboratory findings are an elevated creatinine phosphokinase and leucocytosis. Antipsychotic medication must be stopped immediately and supportive therapy provided, often in an intensive care unit. Treatment includes ensuring hydration and reducing hyperthermia. Dantrolene sodium and bromocriptine may be helpful. Mortality is 20% untreated and 5% with treatment.

Cardiac arrhythmias
Antipsychotic medications cause prolongation of the QTc interval, which may be associated with ventricular tachycardia, torsades de pointes and sudden death. If this occurs, treatment should be reviewed, with careful electrocardiographic monitoring and treatment of serious arrhythmias if necessary.

Psychological treatment
Psychological treatment, including general support for the patient and family, is now seen as an essential component of management. CBT may help patients to cope with symptoms. There is evidence that personal and/or family education, when given as part of an integrated treatment package, reduces the rate of relapse.

Social treatment
After an acute episode of schizophrenia has been controlled by drug therapy, social rehabilitation may be required. Recurrent illness is likely
to cause disruption to patients’ relationships and their ability to manage their accommodation and occupation; consequently, patients with schizophrenia often need help to obtain housing and employment. A graded return to employment and sometimes a period of supported accommodation may be required.

Patients with chronic schizophrenia have particular difficulties and may need long-term, supervised accommodation. This now tends to be in supported accommodation in the community. Patients may also benefit from sheltered employment if they are unable to participate effectively in the labour market. Ongoing contact with a health worker allows monitoring for signs of relapse, sometimes as part of a multidisciplinary team working to agreed plans (the ‘care programme approach’). Partly because of a tendency to inactivity, smoking and a poor diet, patients with chronic schizophrenia are at increased risk of cardiovascular disease, diabetes and stroke, and require proactive medical as well as psychiatric care.

**Prognosis**

About one-third of those who develop an acute schizophrenic episode have a good outcome. One-third develop chronic, incapacitating schizophrenia, and the remainder largely recover after each episode but suffer relapses. Most affected patients cannot work or live independently. Schizophrenia is associated with suicide and up to 10% of patients take their own lives.

**Mood disorders**

Mood or affective disorders include:

- **unipolar depression**: one or more episodes of low mood and associated symptoms
- **bipolar disorder**: episodes of elevated mood interspersed with episodes of depression
- **dysthymia**: chronic low-grade depressed mood without sufficient other symptoms to count as ‘clinically significant’ or ‘major’ depression.

**Depression**

Major depressive disorder has a prevalence of 5% in the general population and approximately 10%–20% in chronically ill medical outpatients, including older adults (see Box 31.6). It is a major cause of disability and suicide. If comorbid with a medical condition, depression magnifies disability, diminishes adherence to medical treatment and rehabilitation, and may even shorten life expectancy.

**Pathogenesis**

There is a genetic predisposition to depression, especially when of early onset. The genetic predisposition is mediated by variants in a large number of genes and loci of small effect rather than mutations in single genes. Adversity and abuse early in life also predispose to depression. Depressive episodes are often, but not always, triggered by stressful life events (especially those that involve loss or imposed change), including medical illnesses. Associated biological factors include hypofunction of monoamine neurotransmitter systems, including 5-HT and noradrenaline (norepinephrine), and abnormalities of the hypothalamic–pituitary–adrenal (HPA) axis, which results in elevated cortisol levels that do not suppress with dexamethasone.

**Diagnosis**

The symptoms are listed in Box 31.8. Depression may be mild, moderate or severe. It may also be recurrent or chronic. It can be both a complication of a medical condition and a cause of MUS (see below), so physical examination is essential; an associated medical condition should always be considered, particularly where there is no past history of depression and no apparent psychological precipitant.

**Investigations**

Investigations are not usually required unless there are clinical grounds for suspicion of an underlying medical disorder, such as Cushing’s syndrome or hypothyroidism.

**Management**

Pharmacological and psychological treatments both work in depression. In practice, the choice is determined by patient preference and local availability. Severe depression complicated by psychotic symptoms, dehydration or suicide risk may require ECT.

**Drug treatment**

Antidepressant drugs are effective in moderate and severe depression, whether it is primary or secondary to a medical illness. The most suitable drug for an individual patient will depend on their previous response, likely side-effects, their concurrent illnesses and potential drug interactions. Commonly used antidepressants are shown in Box 31.28.

The different classes of antidepressant have similar efficacy and about three-quarters of patients respond to treatment. Successful treatment requires the patient to take an appropriate dose of an effective drug for an adequate period. For those who do not respond, a proportion will do so if changed to another class of antidepressant. The patient’s progress must be monitored and, after recovery, treatment should be continued for at least 6–12 months to reduce the high risk of relapse. The dose should then be tapered off over several weeks to avoid discontinuation symptoms. The Scottish Intercollegiate Guidelines Network (SIGN) and National Institute for Health and Care Excellence (NICE) have published treatment guidelines.

**Tricyclic antidepressants**

Tricyclic antidepressant (TCA) agents inhibit re-uptake of the amines noradrenaline (norepinephrine) and 5-HT at synaptic clefts. The

*Higher doses may be required in some patients: see guidelines. With the exception of esketamine, which is given intranasally, other drugs are given orally.
therapeutic effect is noticeable within a week or two. Adverse effects, such as sedation, anticholinergic effects, postural hypotension, lowering of the seizure threshold and cardiotoxicity, can be troublesome during this period. TCAs may be dangerous in overdose and should be used with caution in people who have coexisting heart disease, glaucoma and prostatism.

Selective serotonin re-uptake inhibitors
Selective serotonin reuptake inhibitors (SSRIs) are less cardiotoxic and less sedative than TCAs, and have fewer anticholinergic effects. They are safer in overdose but can still cause QTc prolongation, headache, nausea, anorexia and sexual dysfunction. They can also interact with other drugs increasing serotonin (5-HT), to produce ‘serotonin syndrome’. This is a rare syndrome of neuromuscular hyperactivity, autonomic hyperactivity and agitation, and potentially seizures, hyperthermia, delirium and even death.

Noradrenaline (norepinephrine) re-uptake inhibitors
These agents primarily inhibit noradrenaline uptake at the synaptic cleft but have additional pharmacological effects. Venlafaxine and duloxetine also act as serotonin re-uptake inhibitors, whereas mirtazapine also acts as an antagonist at 5-HT2a, 5-HT2c and 5-HT3 receptors. These drugs have similar efficacy to the agents listed above but a different adverse-effect profile.

Monoamine oxidase inhibitors
Monoamine oxidase inhibitors (MAOIs) increase the availability of neurotransmitters at synaptic clefts by inhibiting metabolism of noradrenaline (norepinephrine) and 5-HT. They are now rarely prescribed in the UK, since they can cause potentially dangerous interactions with drugs such as amphetamines and certain anaesthetic agents, and with foods rich in tyramine (such as cheese and red wine). This is due to accumulation of amines in the systemic circulation, causing a potentially fatal hypertensive crisis.

Esketamine
Esketamine has recently been licensed for treatment-resistant major depressive disorder. It acts as an antagonist at NMDA receptors and is typically used in patients who have not responded to at least two different treatments

ECT and related treatments
Electroconvulsive therapy (ECT) is a highly effective and relatively safe treatment for severe depression but, whilst valuable in the acute setting, its use as a maintenance treatment presents challenges. Transcranial magnetic stimulation (TMS) and the related vagal nerve stimulation (VNS) have shown promise in clinical trials but are not in widespread clinical use.

Psychological treatment
Both CBT and interpersonal therapy are as effective as antidepressants for mild to moderate depression. Antidepressant drugs are, however, preferred for severe depression. Drug and psychological treatments are more effective in combination.

Prognosis
Over 50% of people who have had one depressive episode and over 90% of people who have had three or more episodes will have another. The risk of suicide in an individual who has had a depressive disorder is 10 times greater than in the general population.

Pathogenesis
Bipolar disorder is strongly heritable (approximately 70%). Relatives of patients have an increased incidence of both bipolar and unipolar affective disorder. More than a hundred genetic variants of small effect have been identified by genome-wide association studies. Life events, such as physical illness, sleep deprivation and some medications, such as steroids, may also play a role in triggering episodes.

Diagnosis
The diagnosis is based on clear evidence of episodes of depression and mania. Isolated episodes of hypomania ormania do occur but they are usually preceded or followed by an episode of depression. Psychotic symptoms may occur in both the depressive and the manic phases, with delusions and hallucinations that are usually in keeping with the mood disturbance. This is described as an affective psychosis. Patients who present with symptoms of both bipolar disorder and schizophrenia in equal measure may be given a diagnosis of schizoaffective disorder.

Management
Depression should be treated as described above. If antidepressants are prescribed, however, they should be combined with a mood-stabilising drug (see below) to avoid ‘switching’ the patients into (hypo)manic. Manic episodes and psychotic symptoms usually respond well to antipsychotic drugs (see Box 31.26).

Prophylaxis to prevent recurrent episodes of depression and mania with mood-stabilising agents is important. The main drugs used are lithium and sodium valproate but lamotrigine, olanzapine, quetiapine and risperidone are increasingly employed. Caution must be exercised when stopping these drugs, as a relapse may follow.

Lithium carbonate is the drug of first choice. It is also used for acute mania, and in combination with a tricyclic as an adjuvant treatment for resistant depression. It has a narrow therapeutic range, so regular blood monitoring is required to maintain a serum level of 0.5–1.0mmol/L. Toxic effects include nausea, vomiting, a coarse tremor and convulsions. With long-term treatment, weight gain, hypothyroidism, increased calcium and parathyroid hormone (PTH), nephrogenic diabetes insipidus and renal failure can occur. Thyroid and renal function should be checked before treatment is started and regularly thereafter. Lithium may be teratogenic and should not be prescribed during the first trimester of pregnancy.

Anticonvulsants, such as sodium valproate and lamotrigine, and some antipsychotic drugs can all be used as prophylaxis in bipolar disorder, usually as a second-line alternative to lithium. Valproate conveys a high risk of birth defects and should not be used in women of child-bearing age. Olanzapine can cause significant weight gain. (For a list of the adverse effects of antipsychotic drugs see Box 31.27.)

Prognosis
The relapse rate of bipolar disorder is high, although patients may be perfectly well between episodes. After one episode, the annual average risk of relapse is about 10%–15%, which doubles after more than three episodes. There is a substantially increased lifetime risk of suicide of 5%–10%.

Anxiety disorders
These are characterised by the emotion of anxiety, worrisome thoughts, avoidance behaviours and the somatic symptoms of autonomic arousal. Anxiety disorders are divided into three main subtypes: phobic, paroxysmal (panic) and generalised (Box 31.29). The nature and prominence of the somatic symptoms often lead the patient to present initially to medical services. Anxiety may be stress-related and phobic anxiety may follow an unpleasant incident. Many patients with anxiety also have depression.

Bipolar disorder
Bipolar disorder is an episodic disturbance with interspersed periods of depressed and elevated mood; the latter is known as hypomania when mild or short-lived, or mania when severe or chronic. The lifetime risk of developing bipolar disorder is approximately 1%–2%. Onset is usually in the twenties, and men and women are equally affected.
**Clinical features**

**Phobic anxiety disorder**

A phobia is an abnormal or excessive fear of a specific object or situation, which leads to avoidance of it (such as excessive fear of dying in an air crash, leading to avoidance of flying). A general phobia of going out alone or being in crowded places is called ‘agoraphobia’. Phobic responses can develop to medical procedures such as venepuncture.

**Panic disorder**

Panic disorder describes repeated attacks of severe anxiety, which are not restricted to any particular situation or circumstances. Somatic symptoms, such as chest pain, palpitations and paraesthesia in lips and fingers, are common. The symptoms are in part due to involuntary over-breathing (hyperventilation). Patients with panic attacks often fear that they are suffering from a serious illness, such as a heart attack or stroke, and seek emergency medical attention. Panic disorder may coexist with agoraphobia.

**Generalised anxiety disorder**

This is typically a recurrent or a chronic anxiety state associated with uncontrollable worry. The associated muscle tension often leads to a variety of medical presentations.

**Diagnosis**

The diagnosis is made on the basis of clinical history and typical symptoms, as described above. Where a diagnosis of panic disorder is suspected, it can be confirmed by asking the patient to hyperventilate deliberately for 1–2 minutes and observing whether the symptoms are reproduced. A finding of respiratory alkalosis on arterial blood gas measurement is indicative of chronic hyperventilation.

**Management**

**Psychological treatment**

Explanation and reassurance are essential, especially when patients fear they have a serious medical condition. Specific treatment may be needed. Treatments include relaxation, graded exposure (desensitisation) to feared situations for phobic disorders, and CBT.

**Drug treatment**

Antidepressants are the drugs of first choice. The therapeutic dose can be higher – and response delayed – for anxiety disorders than for depression and there is some evidence that, within their respective classes, escitalopram (SSRI), duloxetine (SNRI) and clomipramine (TCA) have greatest efficacy against anxiety disorders. Activating side-effects of some antidepressants can lead to a worsening of anxiety symptoms in the first 2 weeks and patients should be warned of this.

Benzodiazepines are useful in the short term but regular long-term use carries a high risk of dependence. Regular prescriptions should therefore be limited to 3 weeks; beyond that, prescriptions should be restricted to occasional use as required, with periodic review to guard against dose escalation. Short-acting benzodiazepines, such as lorazepam, have a rapid onset and provide symptomatic relief for up to 2 hours but have the greatest potential for dependence. Longer-acting drugs, such as diazepam, can take an hour to take effect when given orally but provide symptomatic relief for up to 12 hours. The GABA analogue pregabalin is an effective alternative but can also lead to tolerance and dependence. A β-blocker, such as propranolol, can help when somatic symptoms are prominent.

**Obsessive–compulsive disorder**

Obsessive–compulsive disorder (OCD) is characterised by ‘obsessions’ – thoughts, images or impulses that are recurrent, unwanted and usually anxiety-provoking, but recognised as one’s own. In many cases, the obsessions give rise to ‘compulsions’, which are repeated acts performed to relieve the anxiety. Unlike the anxiety disorders discussed above, which are more common in women, OCD is equally common in men and women.

**Clinical features**

Common examples include fears of contamination, giving rise to repeated and ritualised hand-washing, and concerns about having forgotten something, giving rise to time-consuming repeated checking. The differential diagnoses include normal checking behaviour and delusional beliefs about thought possession.

**Diagnosis**

The diagnosis is made on the basis of the typical history, as described above.

**Management**

Obsessive–compulsive disorder usually responds to some degree to antidepressant drugs (high-dose clomipramine or SSRI; see Box 31.28) and to ‘exposure response prevention’ – a form of CBT in which patients are encouraged to expose themselves to the feared thought or situation without performing the anxiety-relieving compulsions. Relapses are common, however, and the condition often becomes chronic.

**Stress-related disorders**

**Acute stress reaction**

Following a traumatic or life-threatening event, such as an assault or a major accident, some people develop a characteristic pattern of symptoms: an initial state of ‘daze’ or bewilderment is followed by altered activity (withdrawal or agitation), often with anxiety. The symptoms are transient and usually resolve completely within a few days. The lay media often describes this as ‘shock’.

**Adjustment disorder**

A more common psychological response to a major stressor such as a serious medical diagnosis is a less severe but more prolonged emotional reaction.

**Clinical features**

The predominant symptom is usually depression and/or anxiety, which is insufficiently persistent or intense to merit a diagnosis of depressive or anxiety disorder. There may also be anger, aggressive behaviour and associated excessive alcohol use. Symptoms develop within a month of the onset of the stress, and their duration and severity reflect the course of the underlying stressor. ‘Pathological grief’ describes a grief reaction that is abnormally intense or persistent, and such abnormalities are a particular type of adjustment disorder. They manifest as a brief period of emotional numbing, followed by a period of distress lasting several weeks, during which sorrow, tearfulness, sleep disturbance, a sense of futility, anger and ‘bargaining’ are common. Perceptual distortions may occur, including misinterpreting sounds as the dead person’s voice or ‘seeing’ the dead person.
Diagnosis
The diagnosis is made on the basis of the typical history, with a strong presumed relationship between the stressful life event and the onset of symptoms described above.

Management
Ongoing contact with and support from a doctor or another person who can listen, reassure, explain and advise are often all that is needed. Most patients do not require psychotropic medication, although benzodiazepines reduce arousal and they and antidepressants can aid sleep.

Post-traumatic stress disorder
Post-traumatic stress disorder (PTSD) is a delayed and/or protracted response to a stressful event of a life-threatening or catastrophic nature. Examples of such events include natural disasters, terrorist activity, serious accidents and witnessing violent deaths. It may also sometimes occur after distressing medical treatments or admissions to intensive care.

Clinical features
The development of PTSD is usually delayed from a few days to several months between the traumatic event and the onset of symptoms. Typical symptoms are recurrent intrusive memories (flashbacks) of the trauma; sleep disturbance, especially nightmares (usually of the traumatic event) from which the patient awakens in a state of anxiety; symptoms of autonomic arousal (anxiety, palpitations, enhanced startle); emotional numbing; and avoidance of situations that evoke memories of the trauma. Anxiety and depression are often associated and excessive use of alcohol or drugs frequently complicates the clinical picture.

Diagnosis
The diagnosis is made on the basis of the typical clinical features following a traumatic life event.

Management
In the immediate aftermath of a significant trauma, the main aim is to provide support, direct advice and the opportunity for emotional catharsis (routine debriefing may actually be harmful). In established PTSD, structured psychological approaches (CBT, eye movement desensitisation and reprocessing (EMDR) and stress management) are effective. Antidepressant drugs are moderately effective.

Prognosis
Most patients recover within 2–3 years. In a small proportion, the symptoms become chronic.

Somatoform disorders
The essential feature of these disorders is that the somatic symptoms are not explained by a medical condition (medically unexplained symptoms, MUS), nor better diagnosed as part of a depressive or anxiety disorder. The derivation of the term ‘somatoform’ is ‘body-like’. Several syndromes are described within this category; there is considerable overlap between them, both in the underlying causes and in the clinical presentation.

Pathogenesis
The cause of somatoform disorders is incompletely understood but contributory factors include depression and anxiety, the erroneous interpretation of somatic symptoms as evidence of disease, excessive concern with physical illness and a tendency to seek medical care. A family history or previous history of a particular condition may have shaped the patient’s beliefs about illness. Doctors may exacerbate the problem, either by dismissing the complaints as non-existent or by over-emphasising and investigating the possibility of disease.

Clinical features
Somatoform disorders can present in several different ways, as described below.

Somatoform autonomic dysfunction
This describes somatic symptoms referable to bodily organs that are largely under the control of the autonomic nervous system. The most common examples involve the cardiovascular system (‘cardiac neurosis’), respiratory system (‘psychogenic hyperventilation’) and gut (‘psychogenic vomiting’ and ‘irritable bowel syndrome’). Antidepressant drugs and CBT may be helpful.

Somatoform pain disorder
This describes severe, persistent pain that cannot be adequately explained by a medical condition. Antidepressant drugs (especially tricyclics and dual action drugs such as duloxetine) are helpful, as are some of the anticonvulsant drugs, particularly carbamazepine, gabapentin and pregabalin. CBT and multidisciplinary pain management teams are also useful.

Chronic fatigue syndrome
Chronic fatigue syndrome (CFS) is characterised by excessive fatigue after minimal physical or mental exertion, poor concentration, dizziness, muscular aches and sleep disturbance. This pattern of symptoms may follow a viral infection such as infectious mononucleosis, influenza or hepatitis. Symptoms overlap with those of depression and anxiety. There is good evidence that many patients improve with carefully graded exercise and with CBT, as long as the benefits of such treatment are carefully explained.

Dissociative conversion disorders
Dissociative conversion disorders are characterised by a loss or distortion of neurological functioning that is not fully explained by organic disease (‘functional neurological disorder’). These may be psychological functions such as memory (‘dissociative amnesia’), sensory functions such as vision (‘dissociative blindness’), or motor functions (‘functional gait disorder’) (Box 31.30). The cause is unknown but there is an association with recent stress and with adverse childhood experiences, including physical and sexual abuse. Organic disease may precipitate dissociation and provide a model for symptoms. For example, non-epileptic seizures often occur in those with epilepsy. Treatment with CBT may be of benefit.

Somatisation disorder
This is defined as the occurrence of multiple medically unexplained physical symptoms affecting several bodily systems. It is also known as Briquet syndrome after the physician who first described the presentation. Symptoms often start in early adult life but somatisation disorder can arise later, usually following an episode of physical illness. The disorder is much more common in women. Patients may undergo a multitude of negative investigations and unhelpful operations, particularly hysterectomy and cholecystectomy. There is no proven treatment except to try to ensure that unnecessary investigations and surgical procedures are avoided to minimise iatrogenic harm.

Hypochondriacal disorder
Patients with this condition have a strong fear or belief that they have a serious, often fatal, disease (such as cancer), and that fear persists despite appropriate medical reassurance. They are typically highly anxious and seek many medical opinions and investigations in futile but repeated attempts to relieve their fears.

| 31.30 Common presentations of dissociative (conversion) disorder |
|---|---|
| Gait disturbance | Non-epileptic seizures |
| Loss of function in limbs | Sensory loss |
| Aphonia | Blindness |
Hypochondriacal disorder often resembles OCD, but in a small proportion of cases the conviction that disease is present reaches delusional intensity. The best-known example is that of parasitic infestation (‘delusional parasitosis’), which leads patients to consult dermatologists. Treatment with CBT can be helpful. Patients who suffer delusions may benefit from antipsychotic medication. The condition may become chronic.

**Body dysmorphic disorder**

This is defined as a preoccupation with bodily shape or appearance, with the belief that one is disfigured in some way (previously known as ‘dysmorphophobia’). People with this condition may make inappropriate requests for cosmetic surgery. Treatment with CBT or antidepressants may be helpful. The belief in disfigulement may sometimes be delusional, in which case antipsychotic drugs can help.

**Management**

The management of the various syndromes of medically unexplained complaints described above is based on the general principles outlined in Box 31.31 and discussed in more detail below.

**Reassurance**

Patients should be asked what they are most worried about. Clearly, it may be unwise to state categorically that the patient does not have any disease, as that is difficult to establish with certainty. However, it can be emphasised that the probability of having a disease is low and that doctors often see patients with physical symptoms but no physical disease. If patients repeatedly ask for reassurance about the same health concern despite reassurance, they may have hypochondriasis.

**Explanation**

Patients need a positive explanation for their symptoms. It is unhelpful to say that symptoms are psychological or ‘all in the mind’. Rather, a term such as ‘functional’ (meaning that the symptoms represent a reversible disturbance of bodily function) may be more acceptable. When possible, it is useful to describe a plausible physiological mechanism that is linked to psychological factors such as stress and implies that the symptoms are reversible. For example, in irritable bowel syndrome, psychological stress results in increased activation of the autonomic nervous system, which leads to constriction of smooth muscle in the gut wall, which in turn causes pain and bowel disturbance.

**Advice**

This should focus on how to overcome factors perpetuating the symptoms: for example, by resolving stressful social problems or by practising relaxation. The doctor can offer to review progress, to prescribe (for example) an antidepressant drug and, if appropriate, to refer for physiotherapy or psychological treatments such as CBT. The attitudes of relatives may need to be addressed if they have adopted an over-protective role, unwittingly reinforcing the patient’s disability.

**Drug treatment**

Antidepressant drugs are often helpful, even if the patient is not depressed.

---

**Psychological treatment**

There is evidence for the effectiveness of CBT. Other psychological treatments such as IPT may also have a role.

**Rehabilitation**

Where there is chronic disability, particularly in dissociative (conversion) disorder, conventional physical rehabilitation may be the best approach.

**Shared care**

Ongoing planned care is required for patients with chronic intractable symptoms, especially those of somatisation disorder. Review by the same specialist, interspersed with visits to the same GP, is probably the best way to avoid unnecessary multiple re-referral for investigation, to ensure that treatable aspects of the patient’s problems, such as depression, are actively managed and to prevent the GP from becoming demoralised.

---

**Eating disorders**

There are two well-defined eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN); they share some overlapping features. Ninety per cent of people affected are female. There is a much higher prevalence of abnormal eating behaviour in the population that does not meet diagnostic criteria for AN or BN but may attract a diagnostic label such as ‘binge eating disorder’. In developed societies, obesity is arguably a much greater problem but is usually considered to be more a disorder of lifestyle or physiology than a psychiatric disorder.

---

**Anorexia nervosa**

The lifetime risk of anorexia nervosa for women living in Europe is approximately 1%–2% (for men it is <0.5%) with a peak age of onset of 15–19 years. Predisposing factors include family (both genetic and shared environmental factors appear to play a role) and ‘neurotic’ personality traits. The illness is often precipitated by weight loss, whether due to non-pathological dieting/increased exercise or physical illness such as gastrointestinal disorders or diabetes mellitus. Many sufferers do not engage with specialist services and it is not uncommon for the first presentation to be with a medical problem (Box 31.32) rather than to psychiatric services.

---

**Clinical features**

There is marked weight loss, arising from food avoidance, often in combination with bingeing, purging, excessive exercise and/or the use of...
diuretics and laxatives. Body image is profoundly disturbed so that, despite emaciation, patients still feel overweight and are terrified of weight gain. These preoccupations are intense and pervasive, and the false beliefs may be held with a conviction approaching the delusional. Anxiety and depressive symptoms are common accompaniments. Downy hair (lanugo) may develop on the back, forearms and cheeks. Extreme starvation is associated with a wide range of physiological and pathological bodily changes. All organ systems may be affected, although the most serious problems are cardiac and skeletal (see Box 31.32).

Pathogenesis

The underlying cause is unclear but probably includes personality (high neuroticism), genetic (twin studies indicate heritability of 0.3–0.5) and environmental factors, including, in many societies, the social pressure on women to be thin.

Diagnosis

Diagnostic criteria are shown in Box 31.33. Differential diagnosis is from other causes of weight loss, including psychiatric disorders such as depression, and medical conditions such as inflammatory bowel disease, malabsorption, hypoplastic anemia and cancer, although it is important to remember that AN can coexist with any of these. The diagnosis is based on a pronounced fear of fatness despite being thin, and on the absence of an adequate alternative explanation for weight loss.

Management

The aims of management are to ensure patients’ physical well-being while helping them to gain weight by addressing the beliefs and behaviours that maintain the low weight. Treatment is usually given on an outpatient basis. Inpatient treatment should be reserved for those at risk of death from medical complications or from suicide. There is a limited evidence base for CBT-based psychological treatments. Family behaviour therapy has efficacy for adolescent but not adult patients. Psychotropic drugs are of no proven benefit in AN but antidepressant medication may be indicated in those with clear-cut comorbid depressive disorder.

Weight gain is best achieved in a collaborative fashion. Compulsory admission and refeeding (including tube feeding) are very occasionally resorted to when patients are at risk of death and other measures have failed. While this may produce a short-term improvement in weight, it rarely changes long-term prognosis.

Prognosis

Two-thirds of patients with AN no longer meet diagnostic criteria at 5-year follow-up. However, long-term follow-up studies suggest that many sufferers continue to have a relatively low body mass index (BMI), suggesting that the symptoms do not completely resolve. Approximately 20% of patients develop a chronic, intractable disorder. Long-term follow-up studies demonstrate that minimum lifetime BMI is the strongest prognostic indicator (BMI <11.5 is associated with a standardised mortality ratio of 4–5). Other indicators of poor prognosis are comorbid BN and atypical demographics (very early or relatively late onset, male gender). Forty per cent of additional deaths are due to suicide, the remainder being due to complications of starvation.

Bulimia nervosa

The prevalence of BN is difficult to determine with precision, as only a small proportion of sufferers come to medical attention. It is believed to be more common than AN, with a similar gender ratio. Peak age of onset is slightly later than for AN, typically late adolescence or early adult life.

Clinical features

Patients with BN are usually at or near normal weight (unlike in AN), but display a morbid fear of fatness associated with disordered eating behaviour. They recurrently embark on eating binges, often followed by corrective measures such as self-induced vomiting.

Diagnosis

Diagnostic criteria are shown in Box 31.33. Physical signs of repeated self-induced vomiting include pitted teeth (from gastric acid), calluses on knuckles (‘Russell’s sign’) and parotid gland enlargement. There are many associated physical complications, including the dental and oesophageal consequences of repeated vomiting, as well as electrolyte abnormalities, cardiac arrhythmias and renal problems (see Box 31.32).

Investigations

Self-induced vomiting and/or abuse of laxatives and diuretics can lead to clinically significant electrolyte disturbances, including hypokalaemia leading to cardiac arrhythmias. Hence it is good practice to measure urea and electrolytes and obtain an ECG whenever these behaviours are prominent in any patient and when BN is suspected in any medical inpatient. Repeated vomiting can also give rise to Mallory–Weiss tears and even oesophageal rupture; if symptoms are suggestive of these, an endoscopy should be performed.

Management

Treatment of bulimia with CBT achieves both short-term and long-term improvements. Guided self-help and IPT may also be of value. There is also evidence for benefit from the SSRI fluoxetine, but high doses of up to 60 mg daily may be required for a prolonged period of up to 1 year; this appears to be independent of the antidepressant effect.

Prognosis

Bulimia is not associated with increased mortality but a proportion of sufferers go on to develop anorexia. At 10-year follow-up, approximately 10% are still unwell, 20% have a subclinical degree of bulimia, and the remainder have recovered.

Personality disorders

Personality refers to the set of characteristics and behavioural traits that best describes an individual’s patterns of interaction with the world. The intensity of particular traits varies from person to person, although certain ones, such as shyness or irritability, are displayed to some degree by most people. A personality disorder (PD) is diagnosed when an individual’s personality causes persistent and severe problems for the person or for others.

Pathogenesis

Some PDs appear to have an inherited aspect (especially schizotypal and paranoid subtypes) but most are more clearly related to adverse childhood experiences.

Clinical features

Personality disorders present in various ways. For example, anxiety may be so pronounced that the individual rarely ventures into any situation where they fear scrutiny. Dissociative traits, such as disregard for the

---

### 31.33 Diagnostic criteria for eating disorders

**Anorexia nervosa**
- Weight loss of at least 15% of total body weight (or body mass index ≤17.5)
- Avoidance of high-calorie foods
- Distortion of body image so that patients regard themselves as fat even when grossly underweight
- Amenorrhoea for at least 3 months

**Bulimia nervosa**
- Recurrent bouts of binge eating
- Lack of self-control over eating during binges
- Self-induced vomiting, purgation or dieting after binges
- Weight maintained within normal limits
well-being of others and a lack of guilt concerning the adverse effects of one’s actions on others, may occur. If pronounced, they may lead to damage to others, to criminal acts or to successful careers, such as in politics. They usually persist throughout life and are not readily treated. While they typically become less extreme with age, they can re-emerge in the context of cognitive decline.

**Diagnosis**

It is possible to classify PD into several subtypes (such as emotionally unstable, antisocial or dependent), depending on the particular behavioural traits in question. A patient who meets diagnostic criteria for one subtype may also meet criteria for others. As allocation to one particular subtype gives little guidance to management or prognosis, classification is of limited value. Diagnosis requires a longitudinal perspective, with clear evidence that the patient's behavioural traits and patterns of interaction with the world have been present throughout their adult life, have been evident across a range of settings and have caused repeated and persistent problems. It can be difficult to achieve this during a single interview, and most psychiatrists warn against making a diagnosis of personality disorder until the patient has been seen several times and corroborative accounts have been obtained. It is common for PD to accompany other psychiatric conditions, making treatment of the latter more difficult and therefore affecting their prognosis.

**Management**

Treatment options are limited but there is some evidence that emotionally unstable PD may respond to dialectical behavioural therapy (DBT). Anxious (avoidant) and obsessional (anankastic) PD may benefit from prescription of anxiolytic drugs, while paranoid/schizotypal PD may be improved by treatment with low doses of antipsychotic agents.

The problematic and inflexible patterns of interaction that characterise a PD are often apparent in the patient’s interaction with health services and can present a challenge to both the service and the patient. Clear clinical communication supported by robust documentation can help to minimise any potential disruption.

**Factitious disorder and malingering**

Factitious disorder describes the repeated and deliberate production of the signs or symptoms of disease to obtain medical care.

**Pathogenesis**

It is difficult to understand what motivates a person to act in this way. Several theories have been proposed but the deception that lies at the heart of the condition makes it difficult to gather accurate data from which to draw reliable conclusions.

**Clinical features**

The disorder feigned is usually medical but can be a psychiatric illness (for example, false reports of hallucinations or symptoms of depression). An example of a medical factitious disorder is dipping of a thermometer into a hot drink to fake a fever. Factitious disorder is uncommon and is important to distinguish from somatoform disorders. A suggested diagnostic algorithm is shown in Figure 31.6.

**Münchausen syndrome**

This refers to a severe chronic form of factitious disorder. Patients characteristically travel widely, sometimes visiting several hospitals in one day. Although the condition is rare, such patients are memorable because they present so dramatically. The history can be convincing enough to persuade doctors to undertake investigations or initiate treatment, including exploratory surgery. It may be possible to trace the patient’s history and show that they have presented similarly elsewhere, often changing name several times. Some emergency departments hold lists of such patients.

![Fig. 31.6 Differential diagnosis of medically unexplained symptoms.](image-url)
Malingering
Malingering is a description of behaviour, not a psychiatric diagnosis. It refers to the deliberate and conscious simulation of signs of disease and disability for an identifiable gain (patients have motives that are clear to them but which they initially conceal from doctors). Examples include the avoidance of burdensome responsibilities (such as work or court appearances) or the pursuit of financial gain (fraudulent claims for benefits or compensation). Malingering can be hard to detect at clinical assessment but is suggested by evasion or inconsistency in the history.

Management
Management is by gentle but firm confrontation with clear evidence of the fabrication of illness, together with an offer of psychological support. Treatment is usually declined but recognition of the condition may help to avoid further iatrogenic harm.

Puerperal psychiatric disorders
There are three important psychiatric presentations following childbirth. When managing these conditions, it is important to always consider both the mother and the baby, and their relationship (Box 31.34).

Post-partum blues
This is characterised by irritability, labile mood and tearfulness. About 80% of women are affected to some degree. Symptoms begin soon after childbirth, typically peak on about the fourth day and then resolve spontaneously within a few weeks. While the aetiology of post-partum blues is not fully understood, it is likely to be related to hormonal or physiological changes associated with childbirth. No treatment is required, other than to reassure the mother and to remain vigilant for development of post-partum depression.

Post-partum depression
This occurs in 10%–15% of women, with onset typically within a month of delivery (although women often suffer for some time before presenting). It can usually be differentiated from post-partum blues by the duration and severity of the symptoms, in particular anhedonia (loss of capacity for pleasure) and negative thoughts. Risk factors include a previous history of depression, a previous history of post-partum depression, antepartum depression and antenatal anxiety. Unlike depression arising at other times, post-partum depression is not more common in lower socioeconomic groups; the prevalence is similar across all social backgrounds. Diagnosis, explanation and re assurance are important. The usual psychological and drug treatments for depression should be considered to minimise the impact on the mother and child at what is a very important time for both. A number of helpful guidelines are available to inform prescribing decisions (see ‘Further information’). The potential risks to both mother and child should be considered and, if hospital admission is required, it should ideally be to a mother and baby unit.

Puerperal psychosis
This has its peak onset in the first 2 weeks after childbirth but can arise several weeks later. It is a rare but serious complication affecting approximately 1 in 500 women. There is a strong association with a personal or familial history of bipolar disorder. It usually takes the form of a manic or depressive psychosis but with sudden onset and fluctuation in severity. Delirium is rare with modern obstetric management but should still be considered in the differential diagnosis. Suspiciousness, concealment and impulsivity are common features of puerperal psychosis; hence the risks to both mother and baby are considerable. The clinical priority is to ensure the safety of both mother and baby and so psychiatric admission, ideally to a psychiatric mother and baby unit, is usually necessary. Pharmacological treatment reflects the clinical picture; antipsychotic medication is almost always indicated, augmented by antidepressants if the picture is of psychotic depression and/or by mood stabilisers if the picture is bipolar. Most women recover but the risk of recurrence following subsequent deliveries is 50% and some women will progress to psychotic episodes not associated with childbirth, usually bipolar disorder.

Psychiatric disorders during pregnancy
Pregnancy can affect the course of psychiatric illnesses and of bipolar affective disorder in particular. Mood-stabilising drugs such as lithium and sodium valproate, which are prescribed for prophylaxis in bipolar disorder, are teratogenic and should be avoided. Most guidelines recommend deferring conception until mood-stabilising medication is not required, or replacing the mood stabiliser with an antipsychotic such as chlorpromazine. Furthermore, the immediate post-partum period is associated with a dramatically increased risk of relapse in bipolar disorder: studies report relapse rates of up to 60% in the first 3 months after delivery in the absence of prophylactic medication. When relapse occurs following childbirth, not only are the stakes higher than at other times but also the onset of illness is more rapid, the symptoms more severe and concealment more pronounced. Post-partum relapse of bipolar disorder requires urgent specialist treatment, usually comprising admission to a psychiatric mother and baby unit. Ideally, women with major mental disorders such as bipolar disorder should be offered expert pre-conception advice to help them make informed decisions about medication and other aspects of their psychiatric care. A comprehensive post-partum risk management plan should be agreed during pregnancy.

Psychiatry and the law
Medicine takes place in a legal framework, made up of legislation (statute law) drafted by parliament or other governing bodies, precedent built up from court judgments over time (case law) and established tradition (common law). Psychiatry is similar to other branches of medicine in the applicability of common and case law but differs in that patients with psychiatric disorders can also be subject to legislative requirements to remain in hospital or to undergo treatments they refuse, such as the administration of antipsychotic drugs to a patient with acute schizophrenia who lacks insight and whose symptoms and/or behaviour pose a risk to himself/herself or to others.

The UK has three different Mental Health Acts, covering England and Wales, Scotland and Northern Ireland, and all of these have recently been revised. Other countries may have very different provisions. It is important for practitioners to be familiar with the relevant provisions that apply in their jurisdictions and are likely to arise in the clinical settings in which they work.

All the countries that make up the UK have also introduced Incapacity Acts in recent years, with detailed provisions covering medical treatments for patients incapable of consenting, whether this incapacity arises from physical or mental illness. In general, the guiding principle in British law is that people should be free to make their own decision about any proposed medical treatment, except where their ability to make and/or
communicate that decision is demonstrably impaired (by mental illness or physical incapacity). Any restrictions or compulsions applied should be the minimum necessary, they should be applied only for as long as is necessary, and there should be a benefit to the patient that balances the restrictions imposed. There should also be provisions for appeals and oversight.

**Multiple Choice Questions**

31.1. When assessing cognitive function within the Mental State Examination, it is good clinical practice to perform which of the following in all patients?

A. A brief assessment of orientation  
B. A brief assessment of orientation and attention  
C. ACE-III  
D. MMSE  
E. MoCA

Answer: B.

It is good practice to perform a brief assessment of orientation (place, person and time – the patient is asked their name, age, date of birth, what building they are in, the current date and day of the week) and attention (‘serial 7’s’ – the patient is asked to subtract 7 from 100 and then 7 from the answer, and so on).

The MoCA (Montreal Cognitive Assessment) and MMSE (Mini-Mental State Examination) are screening questionnaires for cognitive impairment but these are not necessary in every patient, only those in whom cognitive impairment is suspected. The ACE-III (Addenbrooke's Cognitive Examination – 3rd edition) is a more comprehensive cognitive assessment.

31.2. A 26-year-old beauty therapist presents to the Emergency Department with an episode of haematemesis. Upper GI endoscopy reveals a Mallory–Weiss tear. The patient reports that several times each week for the past 6 months she has been bingeing on crisps and chocolate then making herself sick. Her BMI is 26. What would be appropriate first-line medical investigations?

A. FBC, U&Es, LFTs, albumin, cholesterol, amylase, calcium, magnesium, phosphate, fasting glucose, ECG and bone mineral density scan  
B. FBC, U&Es, LFTs, albumin, cholesterol, amylase, calcium, magnesium, phosphate and fasting glucose  
C. FBC, U&Es, calcium, magnesium, phosphate, vitamin B12, folate, ferritin and ECG  
D. FBC, U&Es, calcium, magnesium, phosphate, B12, folate and ferritin  
E. FBC, U&Es, calcium, magnesium, phosphate, B12, folate, ferritin, ECG and bone mineral density scan

Answer: C.

31.3. In the management of psychiatric disorders it is good clinical practice to consider strategies with what framework?

A. Bio-psycho-holistic  
B. Bio-psycho-social  
C. Medico-psycho-social  
D. Medico-psycho-social

Answer: B.

31.4. An 85-year-old man is admitted to an orthopaedic ward with a fractured neck of femur. When attempting to consent the man for his operation, the surgeon soon realises that the man does not understand that he has fractured his hip, nor even that he is in hospital. What term is used to describe this patient’s inability to give informed consent?

A. Cognitive impairment  
B. Delirium  
C. Dementia  
D. Incapacity  
E. Mental deficiency

Answer: D.

‘Cognitive impairment’ is a generic term used to describe any deficit in cognitive function; this man undoubtedly has cognitive impairment. ‘Delirium’ and ‘dementia’ are both diagnoses in which cognitive impairment is a prominent feature. This man may be suffering from either or both. ‘Mental deficiency’ is an outdated term for a failure of intellectual development (the term has been superseded by ‘learning disability’ and ‘mental retardation’).

Consider mother and fetus when prescribing

- Anaemia
- Altered thyroid function tests
- Low creatinine/urea
- Low CO₂
- Raised alkaline phosphatase
- Glycosuria

Remember changes of pregnancy when interpreting laboratory results

Major physiological changes occur during pregnancy, which impact on several organ systems. These are necessary to support the growing fetus, to prepare for delivery and to support lactation. These changes can adversely affect the activity and progression of many pre-existing medical conditions. Emphasising this fact, information from the UK Confidential Enquiry into Maternal Deaths has revealed that over recent years, approximately two-thirds of maternal deaths occur as the result of pre-existing medical conditions, rather than from obstetric causes. The most common causes of death were cardiac disease (23%), venous thromboembolism (16%) and neurological disorders (13%). Although some diseases can undergo remission during pregnancy, others can worsen, potentially jeopardising the health and well-being of the mother and fetus. In this chapter we review the physiological changes that occur during pregnancy and the impact of pregnancy on the diagnosis, clinical course and management of common medical conditions. In addition, we review the pathogenesis and management of several medical conditions specific to pregnancy.

### Planning pregnancy in patients with medical conditions

Patients with pre-existing medical conditions require careful counselling when planning a pregnancy to make them aware of the risks that pregnancy might pose, as well as the changes in symptoms that might be expected to occur during pregnancy. Although each disease is different, as is discussed later in this chapter, the general principles are to ensure that drugs that may be fetotoxic are stopped before pregnancy is attempted; that high-risk patients are kept under close surveillance during their pregnancy; and that new symptoms that emerge during pregnancy are treated seriously and fully investigated where appropriate.

### Functional anatomy and physiology

The most important changes that occur in the anatomy and physiology of major organ systems during pregnancy are discussed below.

#### Bone metabolism

Major changes in bone metabolism take place to meet the demands of the growing fetus. Intestinal calcium absorption increases, due in part to increased production of 1,25-dihydroxyvitamin D (1,25(OH)₂D). Calcium is also released from the maternal skeleton due to increased bone resorption, stimulated by production of parathyroid hormone-related protein (PTHrP) by breast and placenta. This results in loss of bone from the maternal skeleton during pregnancy that continues until lactation ceases and then recovers. Serum concentrations of alkaline phosphatase (ALP) can increase by up to fourfold but this is due to release of ALP from the placenta rather than bone.

#### Cardiovascular system

Heart rate and stroke volume increase during pregnancy; when combined with peripheral vasodilatation and a reduction in systemic blood pressure, this causes a hyperdynamic circulatory state and an increase in cardiac output. Diaphragmatic elevation may affect the electrocardiogram (ECG), causing left axis deviation of up to 15°. Other changes include T-wave inversion in leads III and aV,F, ST depression, small Q waves and a sinus tachycardia. Supraventricular and ventricular beats are common. Echocardiography shows a modest increase in the dimensions of the cardiac chambers.

### Endocrine system

During early pregnancy there is secretion of human chorionic gonadotrophin (hCG) by trophoblast cells, which act on the corpus luteum in the ovary to stimulate oestriol and progesterone production (Fig. 32.1). Levels of hCG rise rapidly during early pregnancy to reach a peak around 8 weeks, and then fall before stabilising at a lower level from 20 weeks until term. There is a progressive rise in oestriol and progesterone levels; initially, these hormones are produced by the corpus luteum but placental production takes over after about 12 weeks. The high levels of gonadal hormones suppress pituitary gonadotrophin production but prolactin levels rise about 10-fold and there is an increase in volume of the anterior pituitary. Serum levels of free T₃ increase during the first trimester but, paradoxically, thyroid-stimulating hormone (TSH) levels fall by almost 50%. This is because hCG is homologous to TSH and mimics the effect of TSH on the thyroid, stimulating both T₃ and T₄ production. The raised levels of T₃ and T₄ feed back to the pituitary and reduce TSH secretion. Later in pregnancy, there is increased degradation of thyroxine by the placenta and levels of thyroxine-binding globulin (TBG) rise, causing the normal range for free T₃ and T₄ to fall progressively during the course of pregnancy. Although TSH levels are difficult to interpret early in pregnancy, they provide the best measure of thyroid function after about 16 weeks’ gestation.

### Gastrointestinal system

The high levels of progesterone during pregnancy lead to relaxation of smooth muscle in the gastrointestinal tract. This causes the lower oesophageal sphincter to relax, predisposing to gastro-oesophageal reflux and reduced gastrointestinal transit; this in turn leads to delayed gastric emptying and constipation.

### Genitourinary system

Glomerular filtration rate (GFR) increases during pregnancy due to an increased cardiac output. By the second trimester, renal perfusion increases by up to 80% and GFR by 50%, leading to a fall in serum urea and creatinine. Mild glycosuria may be observed during normal pregnancy due mainly to an increase in filtered load of glucose. The ureters and renal pelvis are slightly dilated, most prominently on the left side, leading to the physiological hydronephrosis of pregnancy.

### Glucose metabolism

Maternal glucose metabolism changes during pregnancy to optimise delivery of glucose and other nutrients to the fetus. During the second half of pregnancy in particular, there is maternal insulin resistance due largely to an increase in circulating levels of human placental lactogen (hPL) (see Fig. 32.1). The net effect is to ensure that glucose is preferentially supplied to the fetus rather than the mother. Following delivery of the placenta, there is a rapid decline in hPL and reversal of insulin resistance. During pregnancy, fasting plasma glucose decreases slightly, while post-prandial blood glucose may increase. Glycosuria may occur, even in women who do not have diabetes, due to the increased GFR. Insulin secretion in the fetus is driven by fetal glucose levels, which in turn are dependent on maternal glucose concentrations. Accordingly, in women with diabetes, maternal hyperglycaemia stimulates fetal insulin secretion, which increases fetal growth, resulting in increased birth weight or macrosomia.

### Haematological system

Haemoglobin normally falls by about 20% during pregnancy since plasma volume increases more than red cell volume; the so-called physiological anaemia of pregnancy. The reduction in haematocrit lowers
Intriguingly, the increase in blood viscosity but this is offset by an elevation in levels of several clotting factors, resulting in a hypercoagulable state that increases the risk of venous and arterial thrombosis.

Respiratory system

Tidal volume (TV) increases during pregnancy due to an increased vital capacity and reduced residual volume, and by term the increase in TV is about 200mL. These changes are required to meet the 20% increase in oxygen demand that occurs during pregnancy. The $PCO_2$ level decreases but this is offset by an increase in renal excretion of bicarbonate, such that the blood pH remains relatively stable. Respiratory rate is unaffected by pregnancy.

Investigations

The profound changes in physiology and anatomy that occur during pregnancy cause changes in the normal reference ranges for several...
hormones, electrolytes and other analytes, as summarised in Box 32.1. While many investigations can proceed as normal during pregnancy, invasive procedures should generally be avoided unless the potential benefit clearly outweighs the risk. Investigations that can be performed in pregnancy are shown in Box 32.2.

**Imaging**

Imaging during pregnancy should be undertaken only when the clinical benefit outweighs the potential risks to mother and fetus. In suspected pulmonary embolus, radionuclide ventilation/perfusion (V/Q) scanning is preferred over computed tomographic pulmonary angiography (CTPA) in women with a normal chest X-ray since (V/Q) scans expose the maternal breast and lungs to less radiation than CTPA. However, if the chest X-ray is abnormal, CTPA should be performed, since it is more likely to yield a definitive diagnosis. The radiation exposure for both investigations is well below the maximum recommended fetal radiation dose in pregnancy (5 rad). Chest X-rays may also be performed safely at any gestation during pregnancy if clinically indicated, since the radiation exposure is very low for the fetus. Magnetic resonance imaging (MRI) is safe in the second and third trimesters and is useful in the assessment of proximal deep vein thrombosis (DVT) and neurological disorders. However, gadolinium-containing contrast agents should be used only if absolutely necessary. If gadolinium contrast agents are used in women who are breastfeeding, the milk should be discarded for 24 hours. Ultrasound imaging is safe during pregnancy and useful in the assessment of patients with DVT or intra-abdominal pathology.

**Presenting problems in pregnancy**

**Breathlessness**

The causes of breathlessness during pregnancy are summarised in Box 32.3. Many women experience mild breathlessness as part of normal pregnancy, which is known as physiological breathlessness of pregnancy. It is thought to be progesterone-mediated and is classically of gradual onset and present at rest and on exercise. Physiological breathlessness does not require investigation but severe or persistent breathlessness should be investigated, especially if accompanied by chest pain. The diagnostic approach in pregnant patients with suspected pulmonary embolism differs from that in non-pregnant women. Measurement of D-dimer is not helpful since values normally increase progressively throughout pregnancy. Accordingly, the first-line investigation in suspected pulmonary embolism is a (V/Q) scan in a patient with a normal chest X-ray and CTPA in a patient with an abnormal chest X-ray.

Chest pain

Chest pain does not occur during normal pregnancy but the incidences of acute coronary syndrome (ACS) and aortic dissection are both increased. Accordingly, if a pregnant woman develops acute severe chest pain suggestive of either of these conditions, she should be investigated and treated in the same way as a non-pregnant woman.

Nausea and vomiting

Nausea and vomiting are common during the first trimester of pregnancy and do not usually require any specific investigation or treatment. Other causes of nausea and vomiting are summarised in Box 32.4. Severe vomiting with significant weight loss and/or electrolyte disturbance suggests hyperemesis gravidarum, which is discussed in more detail later in this chapter.

Oedema

A mild degree of ankle oedema can occur in normal pregnancy but significant oedema raises suspicion of pre-eclampsia and this should be considered in patients who are also hypertensive and those with proteinuria (Fig. 32.2).

Seizures

The causes and management of seizures during pregnancy are summarised in Box 32.5. An important cause is eclampsia, which should be borne in mind in patients with no previous history of seizures and accompanying features such as hypertension, oedema and proteinuria. Seizures can also occur secondary to electrolyte disturbances associated with hyperemesis gravidarum or hypoglycaemia. Other disorders that are more common during pregnancy and can present with seizures include cerebral venous thrombosis and thrombotic thrombocytopenic purpura (TTP).

Medical disorders in pregnancy

Many disorders present specific management problems before pregnancy, during pregnancy and in the puerperium; the most important of these are discussed in more detail below.
**Hypertension**

Hypertension is one of the most common medical problems during pregnancy, occurring in about 10%–15% of women. The causes and classification are summarised in **Box 32.6**.

### Pre-existing hypertension

If hypertension is discovered during the first half of pregnancy, it usually indicates that there was pre-existing hypertension. This is most likely to be due to essential hypertension but secondary causes also need to be considered. Hypertension during pregnancy should be managed with vasodilators or methyldopa (Box 32.7), taking care to avoid hypotension. Angiotensin-converting enzyme (ACE) inhibitors should be stopped in hypertensive women who are planning to become pregnant and should be avoided during pregnancy since they have fetotoxic effects. Diuretics should also be avoided unless there is heart failure, as they can reduce circulating volume and cause placental hypoperfusion.

### Gestational hypertension

Gestational hypertension usually presents in the second half of pregnancy and most often resolves by 3 months post partum. It should be managed actively with one of the drugs listed in **Box 32.7**, to reduce the risk of progression to pre-eclampsia.

### Pre-eclampsia and eclampsia

Pre-eclampsia is a disorder of vascular endothelial dysfunction that affects about 10% of all pregnancies worldwide. The risk factors for pre-eclampsia are shown in **Box 32.8** and the clinical features illustrated in **Figure 32.2**. Management includes control of blood pressure, administration of magnesium sulphate as prophylaxis against seizures, correction of coagulation abnormalities and monitoring of fluid balance. If pre-eclampsia occurs early in pregnancy, medical management should be initiated with the aim of controlling the condition and maintaining the fetus in utero as long as possible. If these measures are ineffective and eclampsia supervenes (see below), then urgent delivery...
should be considered, provided the fetus is viable, since this results in an immediate cure.

Eclampsia occurs in about 1% of pregnancies and is associated with significant mortality. It usually presents with seizures on a background of pre-eclampsia but rarely can occur before the onset of hypertension and proteinuria. Treatment is with intravenous magnesium sulphate 4 g intravenously over 15 mins followed by an infusion of 1 g/hr titrated to serum magnesium for 24 hr, and delivery of the fetus as soon as possible. Women with pre-eclampsia are more likely to develop hypertension, chronic kidney disease, and cerebrovascular and ischaemic heart disease in later life.

Respiratory disease

Asthma

Women with asthma should be managed aggressively during pregnancy, since poorly controlled asthma is associated with pre-eclampsia, fetal growth restriction, low birth weight and pre-term birth. The management is very similar to that in non-pregnant individuals. Short-acting and long-acting β-agonists, inhaled and oral glucocorticoids, intravenous magnesium and theophylline can be used freely. Biologic agents such as the monoclonal anti-IgE antibody omalizumab can be given for severe allergic asthma. There is less experience with leukotriene receptor agonists during pregnancy but they can be given if necessary. It is advisable to involve an anaesthetist or intensivist at an early stage in patients with severe exacerbations of asthma since airway management is more difficult in late pregnancy.

Respiratory infection

The most common causes of pneumonia during pregnancy are summarised in Box 32.9. Diagnosis and management are broadly the same as in non-pregnant patients. Prompt treatment of infections is important since mothers with pneumonia are more likely to deliver early and have low-birth-weight infants compared with healthy pregnant women.

Bacterial infections

Antibiotics should be given, depending on the causative organism and sensitivities, along with supplemental oxygen and fluids as required. Penicillins, cephalosporins and macrolides such as erythromycin are all safe during pregnancy but tetracyclines should be avoided because they may be fototoxic and can cause staining of the teeth in the fetus (see Box 6.20).

Viral infections

Viral pneumonia is more common and often more severe during pregnancy. Varicella zoster pneumonia in particular is associated with a high fetal and maternal mortality rate. It presents with cough, breathlessness and pyrexia, and is usually preceded by a vesicular rash up to 1 week before. Varicella infection can be diagnosed clinically, with laboratory confirmation by culture or polymerase chain reaction (PCR) of fluid from vesicles, or by serology. Varicella pneumonia causes an interstitial pneumonitis with a characteristic nodular appearance on chest X-ray (p. 1264). Women with confirmed varicella zoster pneumonia should be admitted to hospital for supportive care and treatment with intravenous aciclovir for 7–10 days.

Tuberculosis

Tuberculosis (TB) may occur during pregnancy and in the UK is more common among African and Asian women. Untreated TB is associated with premature delivery and low birth weight. Transmission to the fetus can occur but is unusual. If the diagnosis of TB is confirmed, then antituberculous chemotherapy should be given as normal, since the benefit of treating TB in pregnancy outweighs any potential risks from the medication. A proportion of pregnant women with TB have coexisting human immunodeficiency virus (HIV) infection, which confers a poorer prognosis and also requires treatment with antiretroviral therapy, as described in Chapter 14.

COVID-19

Pregnant women are not disproportionately affected by COVID-19 and should this occur during pregnancy, the same principles of treatment should be followed as for the non-pregnant population.

Gastrointestinal disease

Hyperemesis gravidarum

Hyperemesis gravidarum is a serious condition that affects about 0.5% of pregnant women. It typically presents during the first trimester with severe nausea, vomiting and other clinical features (Box 32.10). It is associated with significant morbidity and mortality, due to malnutrition and electrolyte imbalance. Wernicke’s encephalopathy may develop as the result of thiamin deficiency. Recurrence is common in successive pregnancies. The cause is unknown and the diagnosis is one of exclusion, since alternative causes of severe nausea and vomiting need to be ruled out, particularly if the onset of symptoms occurs after the first trimester. Management is with lifestyle advice and support, intravenous fluids, electrolyte replacement and antiemetics. Thiamin and glucocorticoids may be required in the most severe cases.

Inflammatory bowel disease

Women with inflammatory bowel disease (IBD) should be counselled prior to planning a pregnancy. Medications such as azathioprine, sulfasalazine, 5-aminosalicylic acid (5-ASA), glucocorticoids and tumour
necrosis factor alpha (TNF-α) inhibitors can be continued as normal during pregnancy during the first and second trimesters but methotrexate must be stopped at least 3 months before conception because of its teratogenic effects. Since poorly controlled IBD is associated with an increased risk of pre-term birth, low birth weight and miscarriage, it is important for the disease to be well controlled before conception. The activity of IBD can increase during pregnancy and ulcerative colitis is more likely to flare than Crohn’s disease. Women who experience disease flares should be managed by multidisciplinary teams including medicine and obstetrics, and monitored closely. It is usual to stop TNF-α inhibitors in the third trimester because most drugs in this class are actively transported across the placenta, potentially causing immunosuppression in the neonate. Should TNF-α inhibitors be required in the third trimester, certolizumab pegol is a good choice since it does not cross the placenta in significant amounts. Most women with uncomplicated IBD can have a normal vaginal delivery and do not need a caesarean section, but the need for this should be assessed on an individual basis by obstetric and medical teams.

Diabetes

It is important to institute meticulous glucose control in pregnancy, as maternal diabetes is associated with increased risks of congenital malformations, stillbirth, pre-eclampsia, pre-term delivery, operative delivery, neonatal hypoglycaemia and admission to neonatal intensive care.

Gestational diabetes

Gestational diabetes is defined as diabetes with first onset or recognition during pregnancy. This definition will include a few patients who develop type 1 diabetes during pregnancy, where prompt action and early insulin treatment will be required, and some patients who develop type 2 diabetes, or had unknown pre-existing type 2 diabetes, in whom the diabetes does not remit after pregnancy. However, in most cases, gestational diabetes develops due to an inability to increase insulin secretion adequately to compensate for pregnancy-induced insulin resistance, and most women can expect to return to normal glucose tolerance immediately after pregnancy. Risk factors for gestational diabetes are shown in Box 32.11.

The diagnosis of gestational diabetes is based on maternal blood glucose measurements that are associated with increased fetal growth. An international consensus recommended that glucose values diagnostic of gestational diabetes should be lower than those for non-gestational diabetes (see Box 32.12). Controversy remains about who should be screened, and the screening strategy depends, in part, on the population risk. It is widely accepted that women at high risk for gestational diabetes should have an oral glucose tolerance test at 24–28 weeks, and some guidelines recommend that all high-risk women should be screened by measuring HbA1c, fasting blood glucose or random blood glucose at the first booking visit. It should be noted that measurements of HbA1c cannot reliably be used to diagnose diabetes in early pregnancy and until 3 months post partum, since HbA1c levels fall due to increased red cell turnover.

Management

The aim is to normalise maternal blood glucose concentrations and reduce the risk of excessive fetal growth. The first element of management is dietary modification, in particular by reducing consumption of refined carbohydrate. Women with gestational diabetes should undertake regular pre- and post-prandial self-monitoring of blood glucose, aiming for pre-meal blood glucose levels of < 5.3 mmol/L (96 mg/dL) and a 1-hour post-prandial level of < 7.8 mmol/L (142 mg/dL) or a 2-hour post-prandial level of < 6.4 mmol/L (115 mg/dL). If pharmacological treatment is necessary, metformin, glibenclamide or insulin can all be used. Glibenclamide should be used rather than other sulphonylureas because it does not cross the placenta. Other oral therapies or injectable incretin-based therapies should not be given in pregnancy.

### Risk factors for gestational diabetes

- Body mass index > 30 kg/m²
- Previous macrosomic baby weighing ≥ 4.5 kg
- Previous gestational diabetes
- Family history of diabetes (first-degree relative with diabetes)
- Family origin with a high prevalence of diabetes:
  - South Asian (specifically women whose country of family origin is India, Pakistan or Bangladesh)
  - African Caribbean
  - Middle Eastern

### Diagnosis of gestational diabetes

- Fasting plasma glucose of ≥ 5.1 mmol/L (92 mg/dL)
- 1-hour plasma glucose ≥ 10 mmol/L (180 mg/dL) after a 75 g glucose load
- 2-hour plasma glucose ≥ 8.5 mmol/L (153 mg/dL) after a 75 g glucose load

After delivery, maternal glucose usually returns to pre-pregnancy levels. In the UK, it is currently recommended that women with gestational diabetes should have a fasting blood glucose measured at 6 weeks post partum and have HbA1c concentrations measured annually to screen for the development of diabetes. This is because even those whose glucose tolerance returns to normal post partum are at increased risk for developing type 2 diabetes, with a 5-year risk between 15% and 50%, depending on the population. Therefore, all women who have had gestational diabetes should be given diet and lifestyle advice to reduce their risk of developing type 2 diabetes later in life.

Pregnancy in women with established diabetes

Maternal hyperglycaemia early in pregnancy (during the first 6 weeks post conception) can adversely affect fetal development, causing cardiac, renal and skeletal malformations, of which the caudal regression syndrome (abnormal development of the lower part of the spine) is the most characteristic. The risk of fetal abnormalities is about 2% for non-diabetic women and about 4% for women with well-controlled diabetes (HbA1c < 53 mmol/mol) but more than 20% for those with poor glycaemic control (HbA1c > 97 mmol/mol). Therefore, it is important for women with diabetes to aim to achieve good glycaemic control before becoming pregnant. In addition, high-dose folic acid (5 mg daily, rather than the usual 400 μg) should be initiated before conception to reduce the risk of neural tube defects.

As for gestational diabetes, mothers should attempt to maintain near-normal blood glucose levels while avoiding hypoglycaemia throughout their pregnancy, as this minimises excessive fetal growth and neonatal hyperglycaemia. This is often difficult to achieve, however. Pregnancy is also associated with an increased risk of ketosis, particularly, but not exclusively, in women with type 1 diabetes. Ketoacidosis during pregnancy is dangerous for the mother and is associated with a high rate (10%–35%) of fetal mortality.

Pregnancy is linked with a worsening of diabetic complications, most notably retinopathy and nephropathy, so careful monitoring of eyes and kidneys is required throughout pregnancy. If heavy proteinuria and/or renal dysfunction exist prior to pregnancy, there is a marked increase in the risk of pre-eclampsia, and renal function can deteriorate irreversibly during pregnancy. These risks need to be carefully discussed before a woman with diabetes is considering pregnancy. The outlook for mother and child has been vastly improved over recent years but pregnancy outcomes are still not equivalent to those of non-diabetic mothers. Perinatal mortality rates remain 3–4 times those of the non-diabetic population (at around 30–40 per 1000 pregnancies) and the rate of congenital malformation is increased five- to sixfold.
Endocrine disease

Thyroid disease

Iodine deficiency

Iodine deficiency is a major public health issue in many countries, particularly in South-east Asia, the Western Pacific and Central Africa. Severe iodine deficiency in pregnancy is associated with miscarriage, stillbirth and cretinism, with significant cognitive impairment, gait abnormalities and deafness in the affected child. More moderate iodine deficiency is associated with milder forms of cognitive impairment and affects millions of people. The World Health Organization recommends a daily iodine intake of 250 µg/day for pregnant women. Treatment of iodine deficiency in the first and second trimesters can prevent impaired cognitive development but is less effective if started in the third trimester.

Hypothyroidism

Hypothyroidism occasionally presents during pregnancy, with symptoms such as weight gain, constipation and lethargy, though more commonly, women with hypothyroidism are already diagnosed before they become pregnant. The diagnosis is easily missed since these symptoms are common in normal pregnancy. If suspected, the diagnosis can be confirmed by checking thyroid function tests, which show a raised TSH and low free T4. The reference range for thyroid function tests is different in pregnancy, and results should be checked using a local gestation-specific reference range.

Women with hypothyroidism should aim for optimal disease control before conceiving, and throughout the pregnancy. Untreated hypothyroidism is associated with miscarriage, pre-eclampsia and anaemia. During pregnancy, women should have their thyroid function checked every trimester, and dose adjustments made depending on the results, and blood tests repeated 4–6 weeks after any alterations. Some women may require an increase in their thyroxine dose during pregnancy to maintain normal TSH levels because there is an increased requirement for thyroxine during pregnancy. TSH should be < 2.5mIU/L for women on treatment prior to pregnancy.

Subclinical hypothyroidism is more common. There is no evidence that treating women with subclinical hypothyroidism and negative thyroid peroxidase (TPO) antibodies is beneficial. For TPO antibody-positive women, there are some data to suggest treating TSH above the upper limit of the reference range but less than 10 mIU/L may be beneficial for pregnancy outcome.

Hyperthyroidism

The coexistence of pregnancy and thyrotoxicosis is unusual, since anovulatory cycles are common in thyrotoxic patients and autoimmune disease tends to remit during pregnancy, due to suppression of the maternal immune response. Thyroid function tests must be interpreted in the knowledge that thyroid-binding globulin, and hence total T3 and T4 levels, are increased in pregnancy and that the normal range for TSH is lower (see Box 25.10). Despite this, a fully suppressed TSH is usually indicative of Graves’ disease. When thyroid disease during pregnancy is being dealt with, both mother and fetus must be considered, since maternal thyroid hormones, TSH receptor antibodies (TRAb) and antithyroid drugs can all cross the placenta to some degree, exposing the fetus to the risks of thyrotoxicosis, iatrogenic hypothyroidism and goitre. Moreover, poorly controlled thyrotoxicosis can result in fetal tachycardia, intrauterine growth retardation, prematurity, stillbirth and possibly even congenital malformations.

Antithyroid drugs are the treatment of first choice for thyrotoxicosis in pregnancy. Newly diagnosed hyperthyroidism during pregnancy can be treated with β-adrenoceptor antagonists (β-blockers) in the short term, followed by antithyroid drugs. Propylthiouracil (PTU) is the preferred antithyroid drug because treatment with carbimazole during the first trimester has been associated with the occurrence of choanal atresia and aplasia cutis. Hyperthyroid women who become pregnant while taking carbimazole or PTU should be advised to continue their current drug in pregnancy, with close monitoring. Both carbimazole and PTU cross the placenta and are effective in treating thyrotoxicosis in the fetus caused by transplacental passage of TRAb. To avoid fetal hypothyroidism, which can affect brain development and cause goitre, it is important to use the smallest dose of antithyroid drug (typically < 150 mg PTU or 15 mg carbimazole per day) that will maintain maternal free T3, T4 and TSH concentrations within their respective reference ranges. Thyroid surgery is sometimes necessary because of poor drug adherence, drug hypersensitivity or failure of medical treatment and is most safely performed during the second trimester. Radioactive iodine is absolutely contraindicated throughout pregnancy, as it invariably induces fetal hypothyroidism. Frequent review of mother and fetus (monitoring heart rate and growth) is important during pregnancy and in the puerperium. Serum TRAb levels can be measured in the third trimester to predict the likelihood of neonatal thyrotoxicosis. PTU is the drug of choice in the breastfeeding mother, as it is excreted in the milk to a much lesser extent than carbimazole. Thyroid function should be monitored periodically in the breastfed child.

Post-partum thyroiditis

Post-partum thyroiditis typically presents 3–4 months after delivery. It is discussed in more detail in Chapter 20.

Pituitary disease

Prolactinoma

Prolactinomas are the most common pituitary tumours in young women. Although fertility is reduced in patients with prolactinoma, pregnancies can occur and if this happens the tumour may enlarge as part of the physiological pituitary enlargement that takes place during normal pregnancy. Macroprolactinomas (≥10mm) are at greater risk of enlarging and may cause optic chiasm compression. If women known to have a prolactinoma become pregnant, they should have visual field testing each trimester, followed by pituitary imaging by MRI if enlargement is suspected from changes in visual fields or from symptoms. Measurement of serum prolactin is generally not helpful, since levels increase anyway as part of normal pregnancy. Dopamine receptor agonists such as cabergoline and bromocriptine should normally be stopped during pregnancy, but can be reintroduced if necessary in patients with an enlarging prolactinoma that is threatening the visual fields.

Diabetes insipidus

Women with pre-existing diabetes insipidus may find that their symptoms worsen in pregnancy due to placental production of vasopressinase, a protease that degrades vasopressin (antidiuretic hormone, ADH). Because of this, pregnant women with diabetes insipidus may need higher doses of desmopressin until delivery. The development of symptoms suggestive of diabetes insipidus, such as thirst and polyuria, during pregnancy should raise suspicion of acute fatty liver of pregnancy (AFLP), the syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) or pre-eclampsia, as all of these conditions are also associated with decreased breakdown of vasopressinase by the liver.

Sheehan syndrome

This is a form of post-partum hypopituitarism caused by infarction of the pituitary, usually associated with hypotension from major post-partum haemorrhage. It can present with failure to establish lactation after birth, amenorrhoea or other features of hypopituitarism. The diagnosis can be confirmed by tests of pituitary function and treated with hormone replacement, as described in Chapter 20.

Parathyroid disease

Primary hyperparathyroidism

Primary hyperparathyroidism (PHPT) is uncommon in women of child-bearing age, but if pregnancy does occur in a patient with pre-existing PHPT, careful monitoring is required. Women with mild disease
can be managed conservatively but if serum calcium levels rise above 2.85 mmol/L (11.5 mg/dL), consideration should be given to parathyroidectomy, as fetal mortality is high (up to 40%) in patients with severe hypercalcaemia. If parathyroidectomy is required, it should ideally be performed during the second trimester. Anecdotal evidence suggests that the calcimimetic drug cinacalcet can be used for medical management of PHPT during pregnancy.

**Familial hypocalciuric hypercalcaemia**

Familial hypocalciuric hypercalcaemia (FHH) is a benign disorder caused by mutations in the calcium-sensing receptor, which is described in Chapter 20. Although FHH poses no risk for pregnant women, the hypercalcaemia can suppress PTH secretion in neonates that do not inherit the FHH mutation, resulting in severe hypercalcaemia. Infants of mothers with FHH should have their serum calcium levels monitored during the first few days of life; if hypercalcaemia is detected, intravenous calcium should be given.

**Adrenal disease**

Women with known adrenal insufficiency can continue their glucocorticoid and mineralocorticoid replacement during pregnancy as normal. Rarely, adrenal insufficiency can present for the first time during pregnancy. If this occurs, the diagnosis is challenging because total cortisol normally increases during pregnancy, and short Synachten tests can be falsely normal. Specialist assessment is required. In women with Cushing syndrome who become pregnant, amiloride should be substituted for spironolactone to prevent anti-androgenic effects on a male fetus.

**Human immunodeficiency virus infection**

The course of HIV disease is not altered by pregnancy but treatment with antiretroviral therapy should be given during pregnancy to women who are HIV-positive, as outlined in Chapter 14. In some societies routine HIV testing is recommended at an early stage in pregnancy in all women.

**Inflammatory rheumatic disease**

Most women with inflammatory rheumatic disorders have successful pregnancies but it is critically important for them to be given pre-conception counselling and to review medication use, optimise disease control and make them aware of the risks that pregnancy might pose to their condition and vice versa.

### Rheumatoid arthritis

Women with rheumatoid arthritis should have a medication review; methotrexate, leflunomide, mycophenolate and JAK inhibitors should be stopped and an alternative substituted before conception if necessary (Box 32.13). Rheumatoid arthritis often improves during pregnancy, particularly in those who are negative for rheumatoid factor or anti-cyclic citrullinated peptide antibodies. There is an increased risk of pre-eclampsia, pre-term birth and small babies for women with active disease, emphasising the importance of maintaining disease control during pregnancy. Glucocorticoids, hydrochloroquine, azathioprine and sulfasalazine can all be continued as normal but non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided after 28 weeks (see Box 32.13). Inhibitors of TNF-α are safe during pregnancy and can be continued if necessary to maintain control of the disease. Many TNF-α inhibitors are actively transported across the placenta and this can lead to immunosuppression in the neonate. Accordingly, infants of mothers who have been treated with TNF-α inhibitors during the second and third trimesters should not be given live vaccines and should be monitored closely for any signs of infection, particularly if treatment is continued into the third trimester. An exception is certolizumab pegol, which is a pegylated antibody that is not transported across the placenta but this is used infrequently in IBD. Experience with other biologic therapies such as ustekinumab and vedolizumab during pregnancy is limited, but increasing and clinical experience suggests that these drugs may be used until at least the third trimester. Disease flares are common in the post-partum period, regardless of serology, and this can pose a problem for breastfeeding and care of the infant. Glucocorticoids are a good short-term option to control such flares, pending reintroduction of other disease-modifying antirheumatic drugs (DMARDs) that might have been stopped prior to pregnancy.

### Systemic sclerosis

Pregnancy in women with diffuse systemic sclerosis (SSC), those with pulmonary hypertension or renal involvement and those with disease of recent onset (<4 years) pose risks to mother and fetus. In milder forms of the disease, however, the prognosis is better (Box 32.14). Raynaud’s phenomenon

often improves during pregnancy due to vasodilatation but oesophageal symptoms may worsen. Renal crises are no more frequent during pregnancy, but if one occurs, ACE inhibitors should be given. Although these are normally contraindicated in pregnancy, the potential benefit in this situation outweighs the risk to the fetus. Glucocorticoids, which can be given to promote fetal lung maturation in premature babies, should be avoided in women with SSc where possible because they may provoke renal crisis.

**Systemic lupus erythematosus**

Pregnancy in women with systemic lupus erythematosus (SLE) poses several risks to both mother and fetus, especially if there is renal involvement. There is an increased risk of pre-eclampsia, thrombosis, fetal growth restriction, pre-term delivery, pre-eclampsia, maternal and fetal mortality. If lupus flare during the puerperium. Good control of disease is paramount, since women with SLE who conceive when their disease has been quiescent for at least 6 months are less likely to have complications than those who conceive when their disease has recently been active. It can be difficult to assess disease activity during pregnancy because symptoms such as oedema, hair loss, joint pain and fatigue, which occur in active SLE, are also common during normal pregnancies. The features in Box 32.15 can help differentiate between an SLE flare, normal pregnancy and pre-eclampsia.

All women with SLE should be tested for anti-Ro and anti-La antibodies, since they can cross the placenta and cause neonatal complete heart block or cutaneous lupus, respectively. Medications should be reviewed prior to pregnancy, to ensure they are safe, and an alternative substituted if necessary (see Box 32.13). The management of patients with antiphospholipid antibodies (aPL) is described below.

**Antiphospholipid syndrome**

Primary antiphospholipid syndrome (APS) is associated with an increased risk of adverse pregnancy outcomes, including thrombosis, miscarriage, fetal death and pre-eclampsia. This applies to primary APS and that associated with connective tissue diseases such as SLE. During pregnancy, women with APS should be managed with low-dose aspirin in combination with low-molecular-weight heparin (LMWH).

**Bone disease**

Osteoporosis can rarely present for the first time during pregnancy. This is with either hip or back pain in the third trimester or puerperium due to fractured neck of femur or multiple vertebral fractures, respectively. The cause is unknown but it has been speculated that in some cases this may be due to amplification of the bone loss that normally occurs during pregnancy in women who have pre-existing low bone density. In other women, known risk factors for osteoporosis may be identified such as inflammatory disease or corticosteroids. Pregnancy-associated osteoporosis improves even without treatment but patients with severe disease may be left with chronic back pain due to vertebral deformity. Bisphosphonates and other osteoporosis treatments are often given empirically post partum in an attempt to increase bone density but the effects on fracture outcomes are unclear. Another presentation is with a localised form of osteoporosis affecting the femoral head, which presents with hip pain. This is thought to be a manifestation of chronic regional pain syndrome type 1 (CRPS-1). The diagnosis can be confirmed by MRI scan which shows bone marrow oedema at the affected site. Treatment is symptomatic and the condition usually resolves spontaneously post partum.

**Cardiac disease**

**Congenital heart disease**

Women who have a history of surgically corrected congenital heart disease generally tolerate pregnancy well, but are more likely to have babies with congenital heart disease and should be offered fetal cardiac scans. Acanthocytosis heart diseases, such as atrial septal defect, ventricular septal defect and patent ductus arteriosus, all have a good prognosis in pregnancy. Unrepaired cyanotic heart disease has a very poor prognosis in pregnancy, as does pulmonary hypertension, regardless of the underlying cause. Women with mechanical heart valves require anticoagulation throughout pregnancy but their anticoagulation should be planned with consideration of substituting warfarin with LMWH and aspirin during the first trimester to reduce the risk of warfarin embryopathy. If necessary, warfarin can be used during pregnancy, particularly in the second and third trimesters.

**Valvular heart disease**

The physiological changes of pregnancy may also unmask previously undiagnosed valvular disease. Women with regurgitant lesions, such as mitral regurgitation and aortic regurgitation, tolerate pregnancy better than those with stenotic lesions. Mitral stenosis causes a reduction in blood flow from the left atrium to left ventricle in diastole, which worsens during pregnancy due to the increased heart rate and hypervolaemia. Those with moderate to severe mitral stenosis (valve area < 1.5 cm²) are at particular risk and may develop arrhythmias, tachycardia and pulmonary oedema. Most patients can be managed medically with β-blockers, LMWH and furosemide as necessary. Surgical intervention is indicated if there is continued haemodynamic compromise despite optimal medical management.
### Myocardial infarction

Pregnancy increases the risk of myocardial infarction. While atherosclerosis is the main cause in non-pregnant individuals, coronary artery dissection and coronary thrombosis secondary to the hypercoagulable state are more common causes during pregnancy. Management is similar to that of non-pregnant women, except that statins and glycoprotein IIb/IIIa inhibitors such as ticlopidine should be avoided where possible. Clopidogrel can be given but should be stopped around the time of delivery to reduce the risk of uterine bleeding and to allow spinal anaesthesia to be used if necessary. There is little evidence regarding ticagrelor, an alternative antiplatelet drug, during pregnancy. Stenting can be performed, but bare-metal stents are preferred because drug-eluting stents require dual antiplatelet therapy that cannot be continued around the time of delivery.

### Aortic dissection

Pregnancy is an independent risk factor for aortic dissection and this should be considered when a woman presents with acute severe chest pain during pregnancy. The vast majority of cases in pregnancy are ‘type A’, involving the ascending aorta (see Fig. 16.71), and require careful control of hypertension, caesarean section to deliver the fetus, and emergency surgery to treat the aneurysm.

### Peripartum cardiomyopathy

Peripartum cardiomyopathy (PPCM) presents with heart failure secondary to left ventricular systolic dysfunction towards the end of pregnancy or in the months following delivery. It is a diagnosis of exclusion, made when other causes of heart failure have been ruled out. The cause is unknown but PPCM is more prevalent in women who are older, multiparous, hypertensive and African Caribbean. It is treated by conventional medications for heart failure, including ACE inhibitors if necessary, and delivery of the baby. Many women recover within 3–6 months of diagnosis but the prognosis is variable. There is a significant chance of reduction in cardiac function in subsequent pregnancies.

### Dilated cardiomyopathy

Dilated cardiomyopathy carries a poor prognosis if the pre-pregnancy ejection fraction is below 30% or if symptoms are in New York Heart Association grades 3 or 4. Management is as described for PPCM.

### Renal disease

#### Renal tract infection

Pregnancy predisposes women to urinary tract infection. If asymptomatic bacteriuria is discovered during pregnancy it should be treated promptly with antibiotics, to prevent ascending renal tract infection. Pyelonephritis is more common in pregnancy due to the physiological dilatation of the upper renal tract; if it does occur, it can trigger premature labour.

### Acute kidney injury

Acute kidney injury (AKI) may occur during pregnancy or in the puerperium due to a variety of causes (Box 32.16). Women with AKI caused by pre-eclampsia are prone to pulmonary oedema. Particularly close attention to fluid balance is very important for these women. Intravenous fluid is rarely indicated for women with pre-eclampsia, and most will undergo a diuresis in the days following the diagnosis and the AKI will resolve. If there is a coexisting condition such as sepsis with associated hypotension, then intravenous fluids may be helpful. It is wise to enlist the assistance of critical care medicine specialists early for such patients.

In the post-partum period, AKI may occur as the result of post-partum haemorrhage or pre-eclampsia, and sometimes these occur in combination. Although pre-eclampsia resolves after delivery, AKI can be at its worst in the first few days post partum, especially when exacerbated by obstetric haemorrhage.

### Glomerular disease

Proteinuria caused by glomerular disease is usually exacerbated during pregnancy, and nephrotic syndrome may develop without any alteration in the underlying disease activity in individuals who had only slight

proteinuria before pregnancy. This further increases the risk of venous thromboembolism, the leading cause of maternal deaths in higher-income countries.

### Chronic kidney disease

Women with chronic kidney disease (CKD) are at increased risk of pre-eclampsia, fetal growth restriction, miscarriage, pre-term delivery and fetal death (Fig. 32.3). Pregnancy can also cause acceleration of maternal renal decline. The factors that influence pregnancy outcome for women with CKD are baseline renal function, hypertension, degree of proteinuria and the underlying cause of CKD. Women with CKD should have pre-pregnancy counselling, be closely monitored by a multidisciplinary team throughout pregnancy, and be given low-dose aspirin as prophylaxis against pre-eclampsia.

### Renal replacement therapy

Fertility is reduced among women on renal replacement therapy and there is increased risk of adverse pregnancy outcomes. Despite this, many women receiving renal replacement therapy have successful pregnancies. More intensive dialysis is recommended in pregnancy, and particular attention should be paid to addressing issues around blood pressure, fluid balance and anaemia.

### Renal transplant recipients

Pregnancy should be delayed for a minimum of 12 months following renal transplantation, to allow the graft to stabilise, on minimum immunosuppressive drugs. The outcome is best for women with a well-functioning graft, with no proteinuria or hypertension. Women with renal transplants can deliver vaginally but in practice there is a higher incidence of caesarean section in this group, due to the higher incidence of pre-term delivery.

### Liver disease

Specific causes of liver disease during pregnancy are discussed below.

### Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare and serious condition that typically presents in the third trimester with vomiting, abdominal pain, jaundice and other symptoms (Box 32.17). It is more common in first pregnancies and multiple pregnancies, and is associated with male fetuses. Rarely, fulminant liver failure may occur. The diagnosis can usually be made on the basis of the clinical features, abnormal liver function tests (LFTs) and the appearances of fatty liver on ultrasound. A liver biopsy is rarely needed to make the diagnosis but shows microvascular steatosis. Management is with supportive care and by delivery of the fetus. The development of AFLP has been linked in some cases with an inherited deficiency of the enzyme long-chain acyl-CoA dehydrogenase (LCAD) in the baby.

### HELLP syndrome

The syndrome of haemolysis, elevated liver enzymes and low platelets (HE LLP) is thought to be part of the spectrum of pre-eclampsia. It usually presents antenatally but can also appear for the first time in the postnatal period. The presenting symptoms can be the same as those of pre-eclampsia but can also include headache, right upper quadrant pain and visual disturbance. HELLP can be complicated by liver haematoma and capsular rupture. Management involves supportive care, control of hypertension, correction of coagulopathy and delivery of the fetus.

### Obstetric cholestasis

Obstetric cholestasis is estimated to affect about 1% of pregnancies in women of European descent, although the prevalence is about 1.5% in women of Indian-Asian and Pakistani-Asian descent. The cause is incompletely understood but the condition is thought to be due in part to the cholestatic effect of high oestrogen levels. The typical presentation is in the third trimester with pruritus, particularly affecting the soles and palms. Laboratory testing reveals raised levels of bile acids and abnormal LFTs. The diagnosis can be made on the basis of these clinical features when other causes of liver dysfunction and pruritus have been excluded. Treatment is with ursodeoxycholic acid (UDCA) at a starting dose of 250mg twice daily, to improve symptoms and liver function. However, this treatment does not reduce the risk of adverse fetal outcomes. Rifampicin may be given as an additional therapy if UDCA is ineffective, and vitamin K should be given if clotting is abnormal. Aqueous cream with menthol can also be effective in soothing pruritus. There is an increased risk of fetal mortality with evidence of a particularly high risk when bile acid levels are over 100µmol/L. Some centres induce labour before 40 weeks in an effort to reduce the risk. The risk of recurrence in future pregnancies is high.

---

**Fig. 32.3** Adverse pregnancy outcomes in chronic kidney disease. (Creatinine is in µmol/L. To convert to mg/dL, multiply by 0.011.) Data from Williams D, Davison D. Chronic kidney disease in pregnancy. BMJ 2008; 336:211–215.

**Box 32.17 Criteria for diagnosis of acute fatty liver of pregnancy**

- Vomiting
- Abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin (>14µmol/L >0.82mg/dL)
- Low glucose (<4mmol/L (<72.4mg/dL))
- Elevated urate (>340µmol/L (>5.7mg/dL))
- Leucocytosis (>11x10⁹/L)
- Ascites or bright liver on ultrasound
- Elevated transaminases (alanine/aspartate aminotransferase (ALT/AST) >42U/L)
- Elevated ammonia (>47µmol/L (>81.7mg/dL))
- Renal impairment (creatinine >150µmol/L (>1.7mg/dL))
- Coagulopathy (prothrombin time >14.5 or activated partial thromboplastin time >34 s)
- Microvascular steatosis on liver biopsy

Acute fatty liver of pregnancy can be diagnosed when ≥ 6 of the above features are present in the absence of another explanation.

Viral hepatitis

The course of hepatitis B is unchanged in pregnancy, but it is important to identify women who have active infection to reduce the risk of vertical transmission to the fetus; this risk is up to 90% in women who are hepatitis B e-antigen-positive. Vaccinations and immunoglobulin should be given to infants of mothers who test positive for hepatitis B, and antiviral agents should be given to the mother after delivery. Vertical transmission rates of hepatitis C are low in the absence of HIV infection and so no action is required for the infant, unless there is co-infection with HIV; in this case, antiviral drugs should be considered. Pregnant women are at greater risk of contracting hepatitis E than the non-pregnant population. It is transferred via the faeco-oral route, and is usually a mild self-limiting illness outside of pregnancy. However, it can cause fulminant hepatic failure in up to 20% of pregnant women.

Neurological disease

Epilepsy

Women with epilepsy should have pre-pregnancy counselling, should be advised to take high-dose folic acid from pre-conception, and should have their antiepileptic drugs (AEDs) reviewed. Many AEDs are associated with teratogenicity, and the risk increases with dose and use of multiple medications. Sodium valproate in particular is associated with a 40% risk of persistent neurodevelopmental disorders and a 10% risk of physical birth defects, which is considerably higher than for other AEDs. Ideally, sodium valproate should be avoided in women of child-bearing potential and an alternative AED substituted with a better safety profile, such as lamotrigine, levetiracetam or carbamazepine if it is safe to do so. The minimum number of drugs at the lowest effective dose required for control of epilepsy should be given, and women should be reminded of general safety advice, such as showering instead of bathing. Emergency management of seizures in a pregnant woman with epilepsy (without eclampsia) is the same as that in non-pregnant women. While pregnancy does not generally affect the frequency of seizures in women with well-controlled epilepsy, those who enter pregnancy with poorly controlled epilepsy are likely to deteriorate. The plasma levels of some AEDs such as lamotrigine can fall in pregnancy. Seizures are more common at the time of delivery and women should be advised to deliver in a unit staffed with personnel able to manage this.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) may worsen during pregnancy due to weight gain. Treatment with acetazolamide can be continued during pregnancy but should be avoided in the first trimester due to lack of safety data. Therapeutic lumbar puncture can also be helpful. The mode of delivery is not affected by IIH and spinal analgesia can be given as normal.

Migraine

Migraine often improves during pregnancy but if attacks occur they should be managed with simple analgesia and antiemetics. If necessary, prophylaxis can be given with aspirin, β-blockers or tricyclic antidepressants. Safety data on use of triptans during pregnancy are limited but reassuring. Triptans can therefore be used for the treatment of migraine if other therapies are ineffective.

Stroke

Stroke is twice as common in pregnant women as in non-pregnant women of the same age. The risk is highest during the third trimester and puerperium. The management of stroke during pregnancy is similar to that in non-pregnant patients. The risk of cerebral venous thrombosis is greatly increased during pregnancy. The presentation is with headache, seizures and neurological deficits such as hemiparesis. If the diagnosis is suspected, neuroimaging should be performed with MRI or CT venography. Management of acute infarct should be as for the non-pregnant patient and include consideration of thrombolysis.

Psychiatric disorders

Anaemia

The causes of anaemia during pregnancy are summarised in Box 32.18. Iron deficiency anaemia is most commonly due to a 20% increased demand for iron. In most cases, it responds well to oral iron supplementation, with a rise in haemoglobin of approximately 0.8 g/L per week. If the haemoglobin does not rise following a 4-week trial of iron supplementation, alternative causes of anaemia should be considered. Non-adherence to oral iron is common and intravenous iron should be considered in women with iron deficiency and failure of oral treatment. It is generally not necessary to investigate iron deficiency anaemia during pregnancy unless there is clinical evidence of gastrointestinal blood loss, which should be investigated in the normal way.

Rhesus disease

Women who are negative for the Rhesus antigen should be offered treatment with anti-RhD immunoglobulin around the time of delivery to reduce the risk of haemolytic disease of the newborn. More details are provided in Chapter 25 and Box 25.19.

Thrombocytopenia

The causes of thrombocytopenia during pregnancy are summarised in Box 32.19. The most common cause is gestational thrombocytopenia, which typically occurs towards the end of pregnancy and resolves spontaneously after delivery. It is not associated with adverse pregnancy
outcomes and requires no specific intervention. Pregnancy may occur in women with pre-existing idiopathic thrombocytopenic purpura (ITP). This should be managed with glucocorticoids and/or immunoglobulin, with the aim of maintaining the platelet count above $80 \times 10^9/L$ at the time of delivery, in case spinal anaesthesia or caesarean section is required. Thrombocytopenia may also occur as a component of haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Both are characterised by microangiopathic haemolytic anaemia, acute kidney injury and thrombocytopenia, but in TTP neurological symptoms and fever also occur. These conditions are rare but important to recognise since up to one-quarter of cases occur during pregnancy and the post-partum period. TTP is managed with plasma exchange, fresh frozen plasma and sometimes glucocorticoids or rituximab. Platelet transfusion should be avoided.

### Venous thromboembolism

The risk of venous thromboembolism (VTE) is 4–5 times higher in pregnancy than in non-pregnant women. Women should receive risk assessments for VTE during their pregnancy, based on individualised risk factors (see Box 32.20). On the basis of their personal level of risk, women will be given general advice such as ensuring adequate hydration and mobility, and those at higher risk will be advised to take daily low-molecular-weight heparin (LMWH) during pregnancy and the post-partum period. It is a safe drug in pregnancy, and does not cross the placenta. Deep vein thrombosis (DVT) is the most common presentation and more commonly affects the left leg in pregnancy. Treatment with LMWH should be started once the clinical suspicion has been raised (unless there is a strong contraindication), and diagnostic imaging sought. Measurement of D-dimer is not useful in pregnancy because levels rise as part of normal pregnancy, and clinical decision rules such as Wells score are not validated for use in pregnancy.

Doppler ultrasound scan is the investigation of choice. If the initial Doppler ultrasound scan is negative, and clinical suspicion low, treatment with LMWH can be stopped. However, if the clinical suspicion remains high, treatment can be stopped, and the scan repeated on day 3 and/or day 7. If proximal DVT is suspected, then an MRI of the abdomen should be considered.

Pulmonary embolism (PE) is a significant cause of death in pregnancy. It usually presents with symptoms such as breathlessness, pleuritic chest pain and haemoptysis, and signs such as tachypnoea, tachycardia, hypoxia and hypotension. Initial investigations should include an ECG, CXR and blood tests, including a troponin. Further details of investigations for possible PE are in the Imaging section earlier in this chapter.

Treatment of VTE in pregnancy is with LMWH at a higher dose than outside of pregnancy, based on the patient’s weight. For women with massive PE, systemic or catheter-directed thrombolysis should be considered.

Women with a previous history of VTE who are receiving warfarin or direct oral anticoagulants as prophylaxis should have these stopped prior to conception and LMWH should be substituted. Women on treatment dose LMWH need careful planning around the time of delivery, to balance the need for anticoagulation against bleeding risk from epidural/spinal anaesthetic techniques, and delivery. LMWH and warfarin are both safe in breastfeeding. There is insufficient evidence regarding direct oral anticoagulants in breastfeeding, and they are considered unsafe.

Multiple Choice Questions

32.1. A 32-year-old woman presents at 14 weeks’ gestation to the Emergency Department, with dyspnoea and pleuritic chest pain. Her BP is 70/40 mmHg, heart rate 140 beats/min, respiratory rate is 28 breaths per minute, oxygen saturations 85% on air, and temperature 36.5°C. She undergoes a CTPA scan, which reveals large bilateral pulmonary emboli, with evidence of right heart strain. Which of the following is correct?

A. The fetus should be delivered immediately to aid maternal resuscitation
B. She should be considered for systemic intravenous thrombolysis
C. The patient should be transferred to a specialist cardiothoracic centre
D. The patient should be counselled about direct oral anticoagulants (DOACS)
E. She should be advised against future pregnancy

Answer: B.

This woman has evidence of massive pulmonary emboli, and should be considered for systemic thrombolysis, which is not contraindicated in pregnancy. Delivering the fetus will not alter the resuscitation of this woman, because a fetus at 14 weeks will not cause IVC compression. In addition, this woman has not undergone a cardiac arrest, where a perimortem section is indicated in arrested patients at greater than 20 weeks’ gestation. She does not require transfer, but instead needs urgent management at the hospital she presented to. DOACs are not currently considered safe in pregnancy, and would be inadequate to be the initial treatment for massive pulmonary embol both inside and outside of pregnancy. Future pregnancy is a possibility, with planning and prophylactic low-molecular-weight heparin.

32.2. A 40-year-old woman presents at 30 weeks’ gestation with a swollen left calf. She has a history of protein C deficiency and Crohn’s disease, which has been flaring in the last few weeks. She has been advised to take prophylactic low-molecular-weight heparin, but has struggled with administering the injections. A Doppler ultrasound scan of her left leg is negative. What is the most appropriate course of action?

A. Reassure her and discharge her
B. Demonstrate how to safely administer the injections
C. Admonish her for not taking the injections
D. Repeat the scan on day 3
E. Refer to haematology

Answer: D.

This woman is at high risk of VTE, and has not been receiving adequate prophylaxis. The scan should be repeated on day 3, because clinical suspicion remains high.

32.3. A 23-year-old woman undergoes delivery at 37 weeks’ gestation, having been diagnosed with pre-eclampsia. She has an acute kidney injury (AKI), with a creatinine of 130 µmol/L. There are no other causes and she is euvoaemic. Which of the following is the most appropriate management?

A. Refer to nephrology for consideration of renal replacement therapy
B. Give 250 ml bolus of 0.9% saline, followed by 125 ml/hour and monitor fluid balance closely
C. Advise the patient to drink to thirst, and monitor fluid balance closely
D. Give 1000 ml bolus of Hartmann’s solution, and monitor fluid balance closely
E. Start prednisolone 20 mg once daily, monitor fluid balance closely and repeat bloods daily

Answer: C.

In a euvoaemic patient with an AKI secondary to pre-eclampsia, it is highly likely that she will undergo a diuresis without intervention, and the AKI will resolve. Giving intravenous fluids puts the woman at risk of pulmonary oedema. There is no indication for steroids or renal replacement therapy.

32.4. A 27-year-old woman presents with pruritus at 32 weeks’ gestation. She is diagnosed with obstetric cholestasis (intrahepatic cholestasis of pregnancy). Which of the following statements is true?

A. Her risk in subsequent pregnancies is increased
B. She should be started on ursodeoxyxcholic acid (UDCA) to reduce the risk of stillbirth
C. She is likely to need a caesarean section
D. Vitamin K is contraindicated, so INR can be monitored
E. She should be admitted to hospital for observation

Answer: A.

Women with obstetric cholestasis (OC) are more likely to experience OC in future pregnancies. UDCA may improve her symptoms and liver function, but there is no evidence to show it improves fetal outcomes. There is no indication for caesarean section or admission based on the diagnosis alone and information given. Vitamin K should be given to women to correct coagulopathy.

32.5. A woman with known epilepsy experiences three generalised tonic–clonic seizures, from which she does not recover consciousness in between. She is 13 weeks pregnant and has protein ++ on her urine dip. What is the appropriate emergency drug treatment?

A. IV magnesium sulphate
B. IV lorazepam
C. Buccal midazolam
D. IV phenytoin
E. Rectal diazepam

Answer: B.

This woman is in status epilepticus, and the initial treatment is with intravenous benzodiazepines. She is likely to need additional drugs to gain control of her seizures. IV magnesium is a treatment for eclamptic seizures, but at 13 weeks’ gestation, it is too early in the pregnancy for eclampsia. The protein on her urine dipstick needs to be quantified with laboratory testing, and an explanation sought. Giving buccal therapies is inadvisable in patients with decreased conscious level. IV phenytoin may be needed as an additional therapy, but is not the first or best choice in an emergency. Rectal therapies are not first-line treatment for status epilepticus.

Summary 1293
Historically, childhood illnesses were characterised by a series of acute episodes, often infective, on a background of an otherwise healthy patient. Adult medicine traditionally comprised patients with progressive conditions, and increasing pathology with advancing age. A number of factors have led to the recognition that boundaries between adult medicine and paediatric care are not clear-cut, and recent evidence has confirmed that anticipating and carefully planning the transition of children with long-term conditions (LTCs) into adult services improves care and outcomes. About 14% of children in the industrialised world are diagnosed with an LTC and in the majority of patients the disorder will persist into adulthood. Common illnesses include asthma, epilepsy, congenital heart disease, diabetes and childhood cancer (Box 33.1). Similar trends are developing worldwide, with increasing survival rates of children with complex pathology, and increasing prevalence of lifestyle-related conditions such as obesity, hypertension and type 2 diabetes. Specific factors that make transition planning important in young people with LTCs are outlined in Figure 33.1.

Planning the process of transition from paediatric to adult health services and improving the assessment of young people as they enter those adult services have been shown to impact positively on long-term health outcomes. There is a need for physicians to gain new skills in the care of young people and adults who have conditions that have arisen in childhood. This includes developing specific skills in the management of adolescents and young adults, managing the process of transition and developing knowledge of relevant medical conditions. The overall approach to transition medicine, as well as important disease-specific issues, will be considered in this chapter.

### Transition from paediatric to adult health services

#### Effectiveness of transition planning

A review of the effectiveness of transition planning has confirmed improved health outcomes when specific interventions to improve coordination between adult and paediatric services are implemented. Most research in this field has been undertaken with young people with diabetes, and many of the outcome measures relate to that condition. The principles of transition planning and the potential benefits are, however, likely to be generalisable to other LTCs that present in childhood. Young people with serious LTCs are among the most complex and high-risk patients to care for in adulthood, and it is important to work closely with them as they move to adult services, to try to improve their long-term outcome.

#### General principles of transition planning

Paediatric services are organised and delivered in a very different way to adult medical services. They encompass a period of life that spans from infancy to independence, and progress from taking parents’ views as paramount to needing to recognise the wishes of the young person. After transition, young people move from medical services that have been family-centred and focused around maximising the child’s development, to a service that encourages patient autonomy, in which employment and reproduction are important measures of outcome. At the same time as undergoing transition within medical services, young people are making multiple other transitions in their lives as they move from a dependent to an independent way of living (Fig. 33.2). They often move away from the family home, and parents who formerly held responsibility for patient

management, coordination of care, communication and consent to treatments will be demoted to an advisory role. Paediatric services are not well placed to meet this change in focus from the patient as a child to the patient as an independent adult, and young people benefit from the move to adult services as long as their specific needs as a young adult are recognised.

Principles of prescribing during transition

Hepatic drug metabolism increases from neonatal levels during childhood, eventually decreasing to adult levels after puberty. Once puberty has been completed, adolescents can be considered, in pharmacokinetic and pharmacodynamic terms, to behave like adults. It is important to remember that many young people have considerably lower body mass and therefore body mass index (BMI) than adults, and care needs to be taken to avoid excessive dosage in physically smaller patients. Medicines are often prescribed on a dose per kilogram basis in children, to ensure that they are not exposed to inappropriately high drug concentrations. In young people who are obese (those in whom actual body weight is >20% of their ideal weight), this can potentially lead to problems if the calculated dose per kilogram exceeds the standard adult dose. Accordingly, the ideal weight for the patient’s height rather than actual body weight should be used to calculate drug dosages when prescribing for obese young people. This can be easily done in clinical practice using centile charts to calculate ideal body weight based on the patient’s age and height. Whether or not the patient is obese it is important not to exceed the recommended adult dose when prescribing for young people.

A systematic approach to transition planning

Several steps need to be undertaken to develop a successful programme for transition of care. The key components are summarised in Box 33.2.

33.2 Core elements in developing a transitional care programme

Establishing transition policy
• Develop policy, with input from young people
• Train staff in operation of policy

Tracking and monitoring
• Establish process to identify patients
• Develop systems to track individual progress
• Incorporate transition planning into clinical care

Transition readiness
• Identify suitable adult care provider
• Establish process for introduction to adult team
• Provide written information about joint first consultation

Transition planning
• Ensure communication between paediatric and adult teams
• Identify need for handover consultation
• Prepare written medical handover:
  ▪ Diagnosis
  ▪ Current treatment
  ▪ Previous key issues
• Send relevant information in advance
• Provide information and community support

Transfer to adult services
• Arrange first consultation
• Review transfer package with team
• Identify concerns of young person
• Review young person’s health priorities
• Update medical summary and emergency care plans

Integration into adult services
• Communicate with paediatrics and confirm transfer
• Help young adult to access other adult services
• Continue individualised care plan tailored to young person
• Seek feedback from young adult about transition

The first step is to establish a policy in consultation with young people and train staff in the policy. Subsequently, systems need to be developed to identify patients in need of transition and track them as they pass through the programme. Adult health-care providers need to be identified and processes developed for introducing the young person to the adult team. This should be followed by written communication between the paediatric and adult teams, and then a first consultation with the adult team at which the transfer can be reviewed and a care plan developed. There should subsequently be written communication between the adult and paediatric teams to confirm that handover has occurred, followed eventually by integration of the young person’s care into the adult service.

A number of organisations have published guidelines to planning transition services. Two of the best known include the ‘Ready Steady Go’ programme in the UK and the American Academy of Pediatrics’ ‘Got Transition’ (see ‘Further information’). Details of the sorts of competencies that a young person might need before making a full transition to adult medical services are outlined in Box 33.3.

When should transition happen?

The optimum timing for transition is not specifically defined; it is a process that evolves over a number of years, during which puberty and then adolescence occur. Transition should generally be initiated at around.

33.3 Key features in assessing readiness for transition to adult services

(K) Knowledge
1. Describes condition, effects and prognosis
2. Understands medication purpose and effects
3. Understands treatment purposes and effects
4. Knows key team members and their roles

(S) Self-advocacy
1. Can attend part/whole clinic appointment on their own
2. Knows how to make appointments/alter appointments
3. Has understanding of confidentiality
4. Orders repeat prescriptions
5. Takes some/complete responsibility for medication/other treatment
6. Knows where to get help

(H) Health and lifestyle
1. Understands importance of diet/exercise/dental care
2. Understands impact of smoking/alcohol/substance use
3. Understands sexual health issues/pregnancy/sexually transmitted infections

(A) Activities of daily living
1. Self-care/meal preparation
2. Independent travel/mobility
3. Trips/overnight stays away from home
4. Benefits/financial independence

(V) Vocational
1. Current and future education/impact of condition on career plans
2. School attendance and performance
3. Work experience and access to careers advice
4. Outside activities and interests
5. Disclosure to school/employer

(P) Psychosocial
1. Self-esteem/self-confidence
2. Body/self-image
3. Peer relationships/bullying
4. Support networks/family/disclosure to friends
5. Coping strategies

(T) Transition
1. Understands concept of transition
2. Agrees transition plan
3. Attends transition clinic
4. Visits adult unit (if appropriate)
5. Sees primary care team/other clinical staff independently
12 years of age. Completion time then varies from person to person, also depending on the model of adult services available. Most commonly, full transition occurs between 16 and 18 years of age (Fig. 33.3). This coincides with many other areas where young people are considered to have made the transition to adulthood, such as the completion of formal education.

![Fig. 33.3 Timing of transition.](image)

**Functional anatomy and physiology**

Puberty and adolescence are developmental stages through which children progress during the second decade of life. During this phase, several physical, biochemical and emotional changes occur. The most important are discussed in more detail below.

**Endocrine changes**

The hormonal and physical stages of progression through puberty in males and females are summarised in Figure 33.4. Puberty is initiated by pulsatile increases in gonadotrophin-releasing hormone (GnRH) by the hypothalamus, which in turn stimulates pulsatile release of luteinising hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary. In males, the increased production of LH stimulates Leydig cells in the testes to produce testosterone, and FSH acts on Sertoli cells to stimulate sperm production, as described on page 667 and shown in Figure 20.14. The rise in testosterone increases skeletal growth, promotes development of the male genital organs and stimulates growth of pubic, facial and axillary hair. In females, FSH and LH act on the ovary to promote follicle production, ovulation and menstruation, as described on page 667 and shown in Figure 20.15. Other hormonal changes in all adolescents include a rise in adrenal androgens and a rise in growth hormone, which in turn stimulates production of insulin-like growth factors 1 and 2 (IGF-1 and IGF-2). Insulin production also rises by about 30% during puberty. These hormonal changes contribute to the biological, morphological and psychological changes seen during the teenage years. Adolescence (as opposed to puberty) comprises not only the physical changes of puberty, but also the wider emotional and psychological changes of progression into early adulthood. The emotional and psychological changes are associated with physical maturation but also with sociocultural influences. The feelings and behavioural development of normal adolescence are complex but tend to follow fairly predictable patterns.

**Physical changes**

In girls, there is an increased rate of growth, followed soon after by the development of breasts and pubic hair. Menstruation typically starts after the rate of growth has peaked. In boys, puberty begins with testicular enlargement, followed soon after by a growth spurt and the development of pubic hair. In clinical practice, Tanner staging is used as a method of documenting progression of physical changes that occur during puberty (Fig. 33.5). The average age at onset of puberty in the UK is about 11 years in girls and 12 years in boys, but normal puberty has a very wide range of onset. Factors that are important in predicting age of onset of normal puberty include family history (age of onset is strongly predicted by the parents’ pattern of onset) and body mass, with heavier children entering puberty at a younger age. The current trends towards improved nutritional status and increased obesity in particular are driving earlier onset of puberty. Delayed puberty is defined to have occurred when the age at onset is more than 2.5 standard deviations above the national average, which in the UK is about 13 years in girls and 14 years in boys. If puberty is delayed beyond this point, investigations may be needed to determine the underlying cause. Many children who have had long-term health conditions during childhood experience a delayed onset of puberty because chronic ill health slows longitudinal growth and causes functional hypogonadotropic hypogonadism. Glucocorticoid therapy also contributes to growth retardation in children with chronic inflammatory diseases. An X-ray of the left wrist can be used to assess bone age accurately, and a bone age that is more than 2 years behind the chronological age should prompt consideration of further investigations.

**Cognitive and behavioural changes**

As young people move from their early teenage years to later adolescence there is a move away from the family towards personal independence. This is often characterised by change from a self-centred focus, associated with a sense of awkwardness and worries about being normal, towards increased self-confidence and an awareness of weaknesses in parents and others in authority. In late adolescence, young people reach a stage of self-reliance, increased emotional stability and improved ability to think ideas through. Finally, young adults begin to develop firm belief systems, autonomy and independence. With time, there is reduced conflict with parents and other figures in authority and full maturity develops.

In terms of cognition, there is a transition from being mostly interested in the present, in short-term outcomes and instant gratification, through to increased concern for the future and a greater focus on one’s longer-term role in life. Sexuality and relationships clarity during adolescence, and individuals move from early awkwardness and uncertainty to a firmer sense of their sexual identity, and then development of more serious and longer-term relationships. In terms of morals and values, young people move from a period of risk-taking behaviour and experimentation through to understanding the potential consequences of such behaviour for their future health and well-being. Young adults develop a greater capacity for setting personal goals and an increased focus on self-esteem. Finally, family, social and cultural traditions regain some of their previous importance, and by the time young people emerge from adolescence, they
Acne appears  
Facial hair appears  
Musculature develops  
Larynx enlarges (voice deepens)  
Axillary hair appears  
Some breast enlargement may occur  
Pubic hair appears  
Penis, prostate and seminal vesicles enlarge  
Epiphyseal union hastened

Fig. 33.4 Hormonal events of puberty.  
A In the ovary, FSH acts on granulosa cells to stimulate oestrogen production, whereas LH acts on theca cells to stimulate progesterone production. Androgens are also produced in small amounts by theca cells in response to LH (not shown).  
have usually developed insight and a greater focus on long-term well-being. It is the development of these more mature personality traits that are important for the more active role in health care that is needed for patients to function well within an adult model of medicine. Some young people do vary slightly from these broad patterns but the feelings and behaviours described are, in general, considered normal for each stage of adolescence. Understanding these changes in emotional and psychological behaviour underpins the approaches that are needed to meet the challenges of managing long-term conditions in older adolescents and young adults.

### Investigations

Several changes take place during adolescence in terms of skeletal growth, organ development and body composition, which can influence the interpretation of results. Examples include fusion of the epiphyses as puberty progresses, increases in bone mineral content and density as the skeleton grows, and changes in the reference range of certain biochemical tests. Most of these changes occur gradually during puberty and there are rarely abrupt alterations in adult biochemical concentrations. It is important to use age-adjusted biochemical reference ranges until puberty has been completed. Several biochemical changes take place in the composition of body fluids between infancy and puberty.

Some of the key changes in biochemical markers are outlined in Box 33.4. More detail on reference ranges for specific analytes is provided in Box 35.9. The elevation in alkaline phosphatase (ALP) levels during adolescence relates to the bone isoenzyme produced by osteoblasts in the growing skeleton during the growth spurt. Further investigations for raised levels of ALP are not required in adolescence, as long as other liver function tests, including γ-glutamyl transferase (GGT), are normal.

In general, under normal physiological conditions, the reference ranges of most biochemical tests remain fairly constant between puberty and menopause in women and between puberty and middle age in men.

### Clinical assessment

The initial patient consultation at transition is of vital importance for establishing a potentially life-long professional relationship with the

patient, as well as identifying key features in the history, examination and assessment of their overall needs. Parents commonly attend a first adult appointment with their son or daughter, and it is usually necessary to allow longer for this initial assessment. Often, the first transition appointment is undertaken jointly with the paediatrician in a specialist transition clinic and this will enable a thorough face-to-face handover of all the key facts.

A detailed transition referral letter should clearly describe the diagnosis, current and previous treatments, and key interventions that have been undertaken while the patient was under the care of paediatric services. It is important to check the main details with the young person and to make sure there are no other factors that they feel are of relevance. There are a few features in the history that merit special attention, particularly at the first consultation, as outlined in Box 33.5. Many young people with an LTC attend their first adult outpatient department consultation with their parents, and it is important either to create a time to ask personal and lifestyle-related questions separately from the main history – that is, privately – or to make sure that these can be confidentially explored in future.

### Presenting problems

#### Adherence

Adherence is defined as ‘the extent to which a person’s behaviour, in terms of taking medications, following diets or executing lifestyle changes, coincides with medical or health advice’. The term ‘adherence’ is used in preference to ‘compliance’ because it focuses on whether a person actively adheres to the regimen rather than passively follows the doctor’s orders. It also implies partnership and cooperation between the patient and the care-giver. More recently, clinicians have moved to seeking patients’ concordance with management plans. ‘Concordance’ refers to a consultation process that has an underlying ethos of shared decision-making. It has become clear that current levels of adherence do not deliver the full benefits of medication. Historical paternalistic medical practice does not maximise the chances of patients adopting the changes and treatments they need to improve their outcomes. Reaching a concordant position with patients involves a range of approaches (such as patient-centredness or shared decision-making) and a number of specific actions (such as exploring anxieties about medication side-effects, individualising regimens to suit the patient’s lifestyle, offering a range of treatment options) and has not been evaluated comprehensively.

Adherence to clinic attendance, investigation and treatment often falls significantly in adolescence and during transition to adult services. Measurement of adherence is challenging and reported rates vary according to the method of assessment. Adolescents may also have varying adherence levels within their treatment regimen. An important example is in patients who have undergone organ transplantation, in whom low adherence to immunosuppressive medication is a significant cause of graft rejection and may cause death. Adherence merits careful consideration when caring for adolescents and young adults, and focusing on strategies to improve adherence at this initial stage of patient management can deliver life-long improvements in health outcomes. Young teenagers mainly believe in things that they have directly experienced and do not fully appreciate the unseen consequences of not taking their medications. In time, adolescents learn to

*Throughout the first consultation, confidence and competence in decision-making/capacity to consent should be assessed. If there are concerns about capacity, clarify key decision-makers.
develop hypothetical thinking and to analyse more complex information and decision-making. The ability to engage in formal thinking is inconsistent at first, and at times of stress (such as during an illness) adolescents may regress to more simple ways of problem-solving. Despite their maturing skills, they may remain self-centred and feel invincible. Factors that positively and negatively affect adherence are outlined in Box 33.6. Interventions to improve adherence are summarised in Box 33.7.

Recent literature suggests that two-way communication between patients and professionals about medicines leads to improved satisfaction with care, knowledge of the condition and treatment, adherence, health outcomes and fewer medication-related problems. Younger adults and those coming to adult services following transition from paediatric services have very different expectations in terms of the nature of the patient–doctor relationship and are more likely to require a more collaborative approach to development of management plans to maximise their concordance with treatment in the long term.

**High-risk behaviour**

The high-risk behaviour that can be undertaken by adolescents is well documented and is seen across many cultures. It is important to assess this by history-taking at the time of transition (Box 33.5). Adolescents who have had LTCs during childhood are at greater risk of undertaking harmful behaviour and there is evidence that a poor long-term health outlook is associated with risk-taking behaviour earlier in life.

Globally, the leading causes of death among adolescents are road injury, human immunodeficiency virus (HIV) infection, suicide, lower respiratory infections and interpersonal violence; many of these deaths are linked to risk-taking behaviours such as excess alcohol and drug intake. Quite apart from mortality, there are other significant adverse events linked to risk-taking behaviour in adolescents: excess alcohol ingestion is also associated with non-fatal road traffic accidents, unwanted and unprotected sexual activity, and violence as both perpetrator and victim.

There are a number of theories about the neurodevelopmental changes associated with these behaviour changes. At around 11 years of age, the prefrontal cortex (PFC) and parietal lobes begin a period of pruning of neuronal axons. It is theorised that these changes represent the start of the process of increasing frontal lobe control. A separate process that occurs at the same time predisposes the adolescent to risk-taking behaviour and impulsivity: frontal-striatal reward circuits mature relatively early and encourage the adolescent towards adult activities such as alcohol and drug use, and sexual intercourse, which carry potential health risks. At this stage, the PFC has not yet matured to the point where the individual can assess risk adequately. The PFC and its connections are structurally unable to provide sufficient control. It is thought

**Box 33.6 Factors affecting adherence**

**Negative factors**
- Older adolescent
- Mental health issues with care-giver
- Family conflicts
- Complex therapy
- Medication with side-effects
- Denial of illness

**Positive factors**
- Positive family functioning
- Close friends
- Internal locus of control
- Treatment with immediate benefits
- Patient’s belief in seriousness of illness and efficacy of treatment
- Physician empathy

---

**Box 33.7 SIMPLE strategies to improve adherence**

**Simplify regimen**
- Use once daily/twice daily regimen if possible
- Match regimen to bedtime and meals
- Use pill box or alarms on phone
- Organise services around patient (combined clinics, flexible timing and appointments)

**Import knowledge**
- Share decision-making
- Provide clear instructions:
  - Limit to three or four major points
  - Use simple, everyday language
  - Use written information or pamphlets and verbal education at all encounters
- Supply addresses of quality websites
- Provide advice on how to cope with medication costs

**Modify patient beliefs**
- Empower patients to self-manage their condition:
  - Ask about their needs
  - Ask what might help them become and remain adherent
  - Ensure they understand the risks of not taking their medication
  - Address fears and concerns about taking the medication

**Provide communication**
- Improve interviewing skills
- Practise active listening
- Provide emotional support – treat the whole patient and not just the disease
- Provide clear, direct and thorough information
- Elicit the patient’s input in treatment decisions
- Allow adequate time for patients to ask questions
- Build trust

**Leave the bias**
- Learn more about low health literacy and how it affects patient outcomes
- Consider care of ethnically and socially diverse patient populations
- Acknowledge biases in medical decision-making (intentional or unintentional)
- Address dissonance of patient–provider race/ethnicity and language
- Take extra time to overcome cultural barriers
- Ask specifically about attitudes, beliefs and cultural norms around medication
- Use culturally and linguistically appropriate targeted patient interventions
- Increase engagement, activation and empowerment
- Tailor education to the patient’s level of understanding

**Evaluate adherence**
- Direct:
  - Number of repeat prescriptions
  - Biomarkers of response
  - Measurement of drug levels
- Indirect:
  - Self-reporting: ‘When did you last forget your medicine?’; ‘How often have you forgotten your medicines this week?’

that this maturational gap in PFC control of the pleasure-seeking brain systems is responsible for the risk-taking lifestyle that characterises the period of adolescence.

A number of studies have investigated personality and other factors that contribute to different risk-taking behaviours during adolescence: essentially, younger adolescents and females tend to rate activities as being more risky, and are therefore less likely to undertake them. Older males and those of lower educational status are higher-risk takers. Specific protective factors include high self-esteem and a strong orientation to an internal locus of control; young people who feel they have less control and influence over themselves and their behaviour are more likely to undertake high-risk activities. Many young people with serious long-term health conditions are disempowered in a number of ways and there is evidence that they are predisposed to be high-risk takers during adolescence. Examples of risk-taking behaviour include not only alcohol and drug intake, but also non-adherence to medicines and other aspects of health care, such as diet in diabetes.

It is not easy to affect behaviour during this period of non-adherence. Isolated educational intervention is not sufficient to improve outcome; for example, there is a wealth of evidence showing that adolescents know about the behaviours needed to prevent transmission of HIV, but many do not adhere to this advice. Long-term health-care providers have an invaluable role in supporting adolescents during this period of their development as adults, as many important health-related and lifestyle habits are established during this period: more than 90% of smokers start smoking in adolescence, and life-long habits around eating and exercise are laid down during the teenage years. Focusing on the needs of the emerging adult for autonomy and using the highest levels of communication and patient engagement significantly improve outcomes for patients with LTCs.

### Unplanned pregnancy

In many parts of the world, females commonly undergo their first pregnancy during or just after adolescence. The median age for first pregnancy varies from 19 years in India and parts of Asia, through to 25 years in the United States and around 30 years in Australia and Western Europe. Teenage pregnancy rates are high across the world (Box 33.3.9). Information from the UK suggests that 1 in 6 pregnancies is unplanned, and 1.5% of women between the ages of 18 and 45 face an unplanned pregnancy each year. It is therefore vital to anticipate and discuss the issues surrounding reproductive health with all young people before and during transition, as well as during early adulthood. Young people with serious LTCs have a number of additional factors to be taken into consideration when discussing reproduction, and these discussions need to take place long before a family is planned. General physicians do not need to be able to undertake complex genetic counselling and investigation, but should be able to provide advice about the recurrence risk of common inherited conditions, as well as that of the more common multifactorial LTCs, many of which have an inherited or genetic component.

### Clinical presentations

In almost every clinical setting, there is the potential for a young adult with a serious LTC that has arisen during childhood to present to adult physicians. Medical services can improve the care and outcome for this vulnerable group by planning a systematic approach to transition, as described above, and by focusing the clinical consultation on issues of relevance and importance to each particular patient. The key issues to consider for a number of the most common LTCs of childhood are discussed below.

[Data from: https://data.worldbank.org/indicator/SP.DAC.TFRT.FE]
Neurological disease

Epilepsy

Epilepsy is a chronic disorder, the hallmark of which is recurrent, unprovoked seizures. Epilepsy that has presented during childhood, as opposed to adulthood, is less often associated with underlying central nervous system malignancy and is well controlled with first-line anticonvulsants in around 80% of cases. Young people who still have epilepsy or are on anticonvulsant therapy as they progress into adulthood are more likely to have underlying structural brain disease, such as cerebral palsy, or have more complex or syndromic epilepsy. In many of them, epilepsy may be associated with learning difficulties or other neurological conditions.

Epilepsy presents several problems during transition. Adherence to medication can be an issue and patients with low adherence to epilepsy medicines have higher mortality, higher hospital admission rates and higher Emergency Department attendances. Conversely, high adherence rates at initiation of epilepsy therapy are associated with improved long-term seizure freedom and higher seizure freedom at 4 years. Epilepsy can also affect employment options for young people, as about 30% of patients still have breakthrough seizures while on treatment. Certain types of employment, such as working within the emergency services or armed forces, or becoming a pilot or driver of a heavy goods vehicle, may therefore not be possible. Driving restrictions may also limit options for some other occupations. Young women with epilepsy should be advised that oral contraceptives are less effective with enzyme-inducing antiepileptic drugs; they should also be made aware of the risk of teratogenicity with many antiepileptic drugs, most notably sodium valproate, which should be avoided in pregnancy if at all possible. Pre-conceptual counselling is desirable for all young girls with epilepsy and pre-conceptual folic acid supplementation is advisable to reduce the risk of neural tube defects.

Alcohol use in moderation does not affect seizure control in the majority of patients, but withdrawal from alcohol in dependent patients is epileptogenic and heavy alcohol use should be discouraged. Information about marijuana and epilepsy risk is lacking, but regular marijuana use and excess drinking are associated with poor adherence to medication regimens and increased seizure risk.

Cerebral palsy

Cerebral palsy comprises a range of non-progressive neurological impairments, present from the time of birth or arising in early childhood. Although the neuropathology is non-progressive, the manifestation of problems can evolve, with progressive motor dysfunction related to increased spasticity and possibly progressive seizure activity.

Patients with severe cerebral palsy present specific problems during transition and early adulthood. They may be paraplegic or quadriplegic and most non-ambulatory individuals have significant intellectual disability. This group of patients will be unable to live independently during adulthood and need ongoing long-term care. Delivering medical care to these individuals poses several problems, including practical issues such as consideration of capacity and consent to treatment. Other comorbidities include gastro-oesophageal reflux (often related to abnormal lower oesophageal function), seizures and feeding difficulties often requiring gastrostomy. These individuals usually require a complex care package involving many members of the multidisciplinary team. There are also risks of abuse and neglect in the care of adults with severe disability and this needs to be borne in mind when considering atypical problems or unusual presentations in this vulnerable patient group. Depending on the severity of the patient’s condition, end-of-life care may need to be discussed and planned with the family and other care-givers.

Muscular dystrophy

The muscular dystrophies are a group of diseases that cause progressive weakness and loss of muscle mass. The disorders differ in terms of which muscle groups are affected, the degree of weakness and the rate of disease and symptom progression. All the inherited muscular dystrophies that present during childhood need active management during transition. One of the most important and most severe conditions is Duchenne muscular dystrophy (DMD), which is associated with a progressive decline in mobility, coupled with cardiac dysfunction due to cardiomyopathy, and respiratory failure requiring respiratory support as the disease progresses. Physicians should ensure that the whole family is aware of the wider genetic issues. Female carriers of the DMD gene mutations can suffer muscle fatigue and are at risk of cardiomyopathy, as well as there being obvious risks for their male offspring. On average, patients with DMD survive until their late teens to early twenties, and those with less severe muscular dystrophies, such as Becker dystrophy, survive until their thirties. Although fertility is reduced, young men with these conditions may themselves father children. Male offspring will be unaffected but all female infants of affected males will be carriers.

As the muscular dystrophies progress, a complex package of care involving a multidisciplinary team is necessary; it should include respiratory input to assess the need for ventilatory support, which is a common endpoint for many patients. At the present time, there is no definitive treatment. Glucocorticoids (prednisolone at 0.75 mg/kg/day) have been shown to improve muscle strength and are frequently used, but carry an increased risk of osteoporosis and vertebral fractures. New therapeutic approaches are being developed with the aim of ameliorating disease progression in patients with nonsense mutations. One involves the use of drugs such as ataluren, which promotes binding of transfer RNA (tRNA) molecules at the site of stop codons with a mismatch in one base (near-cognate tRNAs) which results in read-through of the stop codon causing a full-length protein to be produced with an amino acid substitution rather than a truncated non-functional protein. Other potential treatment options for patients with DMD include the use of drugs that are targeted at splice sites to promote exon skipping. Etepliren is one such drug which promotes skipping of exon 51 in patients who have a mutation within this exon. Another is golodirsen, which promotes skipping of exon 53 in patients with mutations in this exon. Another approach that is under investigation is to use idebenone, which is an antioxidant drug that facilitates electron transport in mitochondria. At the moment, however, the evidence for clinical benefit of all of these drugs remains somewhat limited.

Patients with DMD usually require social and financial support. It is important to consider end-of-life care plans with patients and family members. Involvement from palliative care teams, as well as psychological, spiritual and wider non-medical support, is essential.

Respiratory disease

Cystic fibrosis

Cystic fibrosis (CF) is a single-gene autosomal recessive disorder that affects about 1 in 2000 to 1 in 3000 individuals of European descent (p. 510). Clinical manifestations are caused by defects in an ion transporter termed the cystic fibrosis transmembrane conductor regulator (CFTR) protein. With improved supportive care, the median survival in the UK is now more than 50 years. It is well recognised that young people with life-limiting conditions face particular challenges during transition: individuals often exhibit high-risk behaviour during adolescence, and this was particularly true in the past when long-term survival rates were poor. The rates of non-concordance with medication and with time-consuming physiotherapy and nebuliser regimens are high and adversely affect outcome and survival. Exercising tolerance and employment are likely to be restricted as time progresses, and patients need particular support managing the slow decline in function and well-being that occurs throughout their adult lives.

In terms of fertility and child-bearing potential, the picture is complex and merits detailed discussion with patients. It is not often discussed openly by the paediatrician or during childhood, other than with the parents when the patient is young. The vas deferens is absent in 98% of males with CF and seminal vesicular dysfunction means that ejaculates are
low in volume. While boys are infertile, newer reproductive therapies, such as the availability of intracytoplasmic sperm injection, mean that fatherhood is possible. The opportunity for assisted reproduction should be discussed early so that people can make informed choices at an appropriate stage of their lives. Females with CF who have good nutritional status and reasonable health status have normal fertility and genetic counselling should be offered early. Contraception needs to be discussed with women who are not planning a pregnancy, since pulmonary hypertension is an absolute contraindication for the oral contraceptive pill (OCP). Women also need to be advised about the effects of antibiotics on OCP effectiveness. New orally available small-molecule therapies, including lumacaftor and vibacaftor, have recently been licensed; they can partially rectify functional defects in the CFTR and have improved outcomes. These drugs are having a positive effect on symptom control and are potentially disease-modifying. The triple drug combination of eluxacaftor–tezacaftor–vibacaftor is an important new therapy for individuals who have at least one F508del mutation, which includes approximately 85% of people with CF in the United States. Other therapeutic approaches, including gene therapy and mRNA-editing therapies, are also being explored as treatments for CF. Common issues encountered during transition of CF patients are summarised in Box 17.34.

Cardiovascular disease

Congenital heart disease (CHD) is the most common congenital anomaly, affecting about 1% of live births. Among birth defects, CHD is the leading cause of mortality. Maternal illnesses such as rubella and injection of teratogenic agents during pregnancy, along with paternal age, all play roles in pathogenesis. Although some chromosomal anomalies, such as trisomy 13, 18 and 21 and monosomy X (Turner syndrome), are strongly associated with CHD, these account for only 5% of cases. Microdeletion and single-gene mutations can also be important, such as in DiGeorge syndrome (22q11.2 microdeletion). Overall, the most common congenital valvular anomalies are aortic and pulmonary stenosis. The most common structural anomaly is ventricular septal defect.

There is a wide range of severity of CHD but many patients with life-limiting conditions (usually complex structural anomalies such as tetralogy of Fallot or hypoplastic left heart syndrome) survive to adulthood. Genetic counselling of affected individuals is important, as there is a 1%–2% recurrence risk of any cardiac anomaly in offspring. Affected patients should be transitioned to a cardiologist with experience in CHD since this has become a subspecialty in own right. More details are provided on page 465 and in Box 16.103.

Hypertrophic obstructive cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM) is characterised by left ventricular wall hypertrophy, impaired diastolic filling and abnormalities of the mitral valve. These features can cause dynamic obstruction of the left ventricular outflow tract, diastolic dysfunction, myocardial dysfunction and an increased risk of supraventricular and ventricular tachyarrhythmias. HOCM is a genetic disorder caused by mutations affecting the genes that encode cardiac sarcomere proteins and is most frequently transmitted as an autosomal dominant trait. It may present for the first time during adolescence with cardiac arrest or sudden cardiac death. Predictive genetic testing is possible but challenging because of the large number of causal mutations. In clinical practice, careful analysis of the family history can be useful in identifying those at risk of inheriting the disease. If no gene anomaly has been identified within a family, first-degree relatives may need screening by electrocardiography (ECG) and echocardiography. Identification of a genetic anomaly is most helpful in allowing identification of family members who do not need echocardiograms or clinical follow-up. Children of affected parents should be screened every 3 years until puberty, and then annually until 20 years of age. If there is no evidence of HOCM in early adulthood, it is unlikely that the condition will develop in later life.

Oncology

Around 1 child in 500 will develop cancer by the age of 14 years. Leukaemia is the most common, accounting for about 33% of cases; central nervous system tumours are the next most common, accounting for around 25% of all childhood cancers. Fifty years ago, 75% of children diagnosed with cancer died, but overall survival rates now range from 75% to 80%. Between 60% and 70% of young adults who have survived childhood cancer will develop at least one medical disability, most commonly as a result of their therapy rather than their primary cancer. There is a three- to sixfold increased risk of a second cancer, with an absolute risk of about 10% before 50 years of age. It is therefore important for these individuals to be kept under surveillance during transition and beyond.

Endocrine and reproductive disturbances are the most common late effects, affecting 40%–60% of survivors. Infertility can be an issue in both males and females receiving cytotoxic medications, unless it has been possible to store semen and ovarian tissue in advance of treatment. Other long-term risks include hypopituitarism, growth hormone deficiency and pubertal delay (especially in boys) from brain irradiation. Radiotherapy to the neck can cause hypothyroidism and increases the risk of thyroid cancer. Total body irradiation offered as conditioning for bone marrow transplantation affects both ovarian and testicular function, and many of the chemotherapy agents used have adverse effects on fertility. Chemotherapy-induced ovarian failure is typically associated with high-dose alkylating agents such as cyclophosphamide, and this is an independent risk factor for premature ovarian failure. In recent years, patients have been offered ovarian and testicular tissue retention and fertility issues are being discussed with families during childhood, but often the patients themselves have limited levels of knowledge of the details. Chemotherapy and radiotherapy in childhood significantly reduce ovarian reserves. When combined with the progressive ovarian decline that occurs in all women throughout adulthood there is a significant risk of premature menopause or ovarian failure, with 8% of survivors affected. Young women need to be aware of these risks during their early adulthood to help with family and lifestyle planning; for example, they may wish to plan to have children earlier in their adult life rather than risking ovarian decline.

Cardiomyopathy is another complication of anthracyclines such as doxorubicin and daunorubicin. Serious cardiac complications include arrhythmias, dilated cardiomyopathy from myocardial necrosis, and angina or myocardial infarction arising from vaso-occlusion or vasospasm.

In addition to physical effects, children who have faced life-threatening illness in childhood may experience psychological and family difficulties during adulthood. Cognitive impairment is more common in children who have received chemotherapy or radiotherapy to the brain, and problems can include lower IQ, problems with memory and attention, poor hand-eye coordination and behaviour or personality problems, combined with the well-recognised and physical complications of cancer treatment in childhood.

Increasing recognition of these issues has resulted in active monitoring programmes for survivors of childhood cancer, who are best seen in specialist ‘late effects’ multidisciplinary clinics, where teams include oncologists, psychologists and specialists from other relevant disciplines.

Renal disease

Chronic kidney disease (CKD) accounts for some of the most complex long-term illnesses in childhood. The most common causes during childhood and adolescence are shown in Box 33.10. The primary pathology can be varied and many conditions have no specific treatment, but the overall approach to management of progressive renal insufficiency is the same. Internationally agreed definitions of CKD staging in children differ
asthma treated with inhaled glucocorticoids, an average height reduction of 1.2 cm is reported. This can also be associated with delayed puberty, as well as an increased risk of osteoporosis in adulthood. Post-transplant lymphoproliferative disorders (PTLDs) are well-recognised and potentially life-threatening complication in solid organ recipients. PTLD is the most common malignancy complicating solid organ transplantation, accounting for 20% of all cancers. They represent a range of lymphoproliferative disorders, from infectious mononucleosis and lymphoid hyperplasia to malignant lymphoma. Most cases of PTLD are associated with Epstein–Barr virus (EBV), leading to uncontrolled B-cell proliferation and tumour formation. Up to 10% of solid organ transplant recipients develop PTLD but the risk is almost four times higher in patients under 20 years of age, as opposed to those aged 20–50. This increased risk relates mainly to the development of EBV infection after transplantation; most adults are already EBV-seropositive at the time of transplantation and therefore at lower risk of this complication. The type of organ transplant that has been undertaken predicts PTLD risk, with the cumulative incidence over 5 years ranging from 1% to 2% in haematopoietic cell transplant and liver transplants, 1%–3% in renal transplants, 2%–6% in heart transplants and 2%–9% in lung transplants to as high as 11%–33% in intestinal or multi-organ transplants. The different rates possibly relate to the varying degrees of immunosuppression required. The incidence of PTLD is highest in the first year after transplantation, when it is associated with the highest levels of immunosuppression.

**Organ transplantation**

Children requiring renal replacement therapy are the most common recipients of kidney transplants in childhood. Liver and heart transplantation, followed by lung and small bowel transplantation, are well recognised but less commonly undertaken procedures. Non-adherence to immunosuppressive regimens during adolescence is a well-known risk factor for graft failure. The reported incidence of graft failure due to non-adherence is 10%–15% but this is likely to be an under-estimate. Rates of non-adherence are highest among adolescents and young adults. As well as non-adherence to immunosuppression, non-adherence to testing and clinic attendance adversely affects the care and outcome of around 1 in 8 kidney transplant patients. Poor adherence is associated with patients with worse psychological status and family dysfunction; adherence has been shown to improve with education and increased motivational factors, as might be expected. This offers the opportunity to improve graft survival. At present, 50% of cadaveric grafts and around 88% of live donor grafts are still functioning 10 years post transplant. There is no clear difference between children and adults in survival of transplanted kidneys.

Many medications used in transplant medicine and in renal disease can have long-term effects on health. Inhibition of linear growth is seen even with low doses of glucocorticoids, such as prednisolone 0.125 mg/kg/day on a long-term basis. Alternate-day regimens are generally considered preferable in childhood. The height reduction associated with long-term glucocorticoid use in childhood is dose-dependent, and even for children with
include exclusive enteral nutrition for 6–8 weeks using a whole-protein (polymeric) formula, which induces initial remission in 80% of children. This is equivalent to glucocorticoid therapy but offers improved nutritional status and superior mucosal healing. Glucocorticoids can also be used to induce remission, as well as to treat exacerbations, but should be followed up by immunosuppressive therapy with azathioprine or methotrexate. Adolescents and children are more likely than adults to require biologics and around 20% need treatment with tumour necrosis factor alpha (TNF-α) inhibitors such as infliximab or adalimumab. Around 20% of children with CD require surgery within 5 years of diagnosis; limited resections and strictureplasty are considered best practice to preserve gut length and prevent short bowel syndrome.

Children with ulcerative colitis (UC) are more likely than adults to present with pancolitis (approximately 80% versus 40%–50% in adults). Mild disease should be treated initially with oral 5-ASA preparations such as mesalamine or sulfasalazine. If the response is inadequate, oral glucocorticoids can be used, but caution must be exercised because of the adverse effects on skeletal growth and bone mineral density. Thiopurines such as 6-mercaptopurine or azathioprine are frequently used as steroid-sparing agents, with progression to anti-TNF-α therapy for those who still do not respond. There is less evidence for efficacy of TNF-α inhibitors in adolescents with UC than those with CD; they seem to be effective at inducing an initial response but less useful for maintaining long-term remission, since a significant proportion of patients still require colectomy (20% at 1 year) or long-term glucocorticoids. Ciclosporin is probably more effective than infliximab in adolescents with refractory UC. As with other young people who have long-term conditions, adherence to medication is particularly important to reduce the risk of relapse. In terms of lifestyle advice, smoking is a particular risk as it increases both the rate and severity of relapses. Body image can be a particular challenge for young adults with IBD, and those with colostomies or fistulae, for example, can find this part of their illness particularly difficult. Delays puberty and short stature are important comorbidities, partly related to medication side-effects and also to the nature of the inflammatory bowel disease itself.

**Rheumatology and bone disease**

**Juvenile idiopathic arthritis**

Juvenile idiopathic arthritis (JIA) is the term used to describe a wide variety of inflammatory rheumatic diseases that present during childhood. Oligoarticular juvenile arthritis has a good prognosis and often remits during adulthood, and so transitioning patients to adult rheumatology services may not always be required. The same does not hold true for systemic JIA and polyarticular JIA, which often require long-term immunosuppressive therapy through transition and beyond into adulthood. Smoking is a risk because it increases the activity of inflammatory disease and reduces the effectiveness of biologics. Adherence to and concordance with medication remain a challenge, as in other chronic diseases. Functional limitation secondary to joint damage may limit employment opportunities. Contraceptive advice is important in patients on methotrexate.

**Glucocorticoid-induced osteoporosis**

Osteoporosis is a complication of long-term glucocorticoid therapy that may be required in patients with inflammatory disease, transplantation and DMD.

There is paucity of evidence about best practice in glucocorticoid-induced osteoporosis in children and adolescents, but in general the teenage years are a period of considerable bone mineral deposition and offer a chance to enhance bone mineral density significantly. It is important to ensure adequate calcium and vitamin D intake and to supplement if necessary. Therapy with bisphosphonates is often initiated in patients with clinical vertebral fractures although the evidence base for prevention of fractures with treatment in childhood and adolescence is limited.

**Osteogenesis imperfecta**

Osteogenesis imperfecta (OI) is a genetic disorder most commonly caused by mutations in the type 1 collagen genes which typically presents with multiple low-trauma fractures during infancy and childhood. The incidence of fractures falls substantially in adolescence, probably because of the increase in bone mass which occurs as the result of skeletal growth. However, the incidence of fractures in OI during transition and in young adults is about 10–100 times higher throughout life as compared with the general population. Intravenous bisphosphonates such as pamidronate and zoledronic acid are widely used in the treatment of children with osteogenesis imperfecta (those with long-bone deformities, vertebral compression fractures, and three or more fractures per year, in whom the benefit/risk ratio is thought to be positive), although the evidence base for prevention of fractures is poor and mainly based on observational studies.

There is much debate about whether continuing bisphosphonate therapy into adulthood is beneficial due to concerns about suppression of bone turnover in the long term. Affected individuals and their parents can find this change in treatment strategy confusing and it is important to explain the underlying rationale in order to manage expectations.

**Hypophosphataemic rickets**

Hypophosphataemic rickets is a rare genetic disorder caused by mutations in genes that regulate phosphate excretion. Adherence to phosphate supplements and, to a lesser extent, vitamin D metabolites represents an important issue in optimising management during childhood and this becomes even more challenging in transitioning patients. The treatment of X-linked hypophosphataemic rickets (XLH) in children has, however, been revolutionised by burosumab, a neutralising antibody to FGF23 given by subcutaneous injection once monthly which corrects the metabolic disorder and has been shown in clinical trials to be significantly more effective in the treatment of XLH than standard care. While skeletal deformity does not progress following closure of the epiphyses, different problems arise in adolescent patients when there is suboptimal control of hypophosphataemia, including painful pseudofractures and arthralgia associated with entheseopathy. The renal phosphate leak tends to improve to an extent during adolescence and early adulthood and the requirement for phosphate is reduced, but many patients still require treatment in adulthood.

**Summary**

Young people who have suffered long-term conditions during childhood represent a particularly high-risk group of patients as they progress through adolescence to become young and, finally, mature adults. They bring with them specific medical risks and complications related to their previous medical treatment, and knowledge of these is important to identify the long-term complications of the therapies to which they have been exposed. They are a patient group that can display complex and often abnormal illness behaviour. Understanding this and implementing an effective process for transition from paediatric to adult services can reduce the significant risks that these patients face in early adulthood. As they mature and develop more adult intellectual and emotional behaviour patterns, the risks to their health and well-being reduce. Patients in transition can be a particularly
challenging group to manage, but investment of time and effort at this stage of their lives can be extremely rewarding and can bring significant improvements in long-term health-related outcomes.

Multiple Choice Questions

33.1. When considering renal transplant rejection rates in children, kidney survival rates are better in:

A. Males
B. Older adolescents
C. Patients who have not been dialysed prior to transplantation
D. A parent donor rather than a sibling
E. A deceased donor under 2 years old rather than an older donor

Answer: C.

Five- and 10-year kidney survival rates have improved steadily in recent years, such that organ survival rates are now around 80% and 60%, respectively. Much of this has been delivered through improved immunosuppressive regimens, but there are patient-specific factors that also affect kidney survival. A worrisome outlook is seen in females, children of African and Caribbean origin and older adolescents in whom adherence is less good and transition to adult services is a negative factor. Kidney survival rates in general are better for living rather than deceased donors, but children rarely have brothers or sisters (some of whom are HLA identical) old enough to be an organ donor; as a result, most long-donated allografts are from a parent, who is an obligate one haplotype match. Optimal HLA matching is important to minimize sensitization, particularly for young recipients who will need retransplantations in later life. The best 5-year graft survival (90%) in paediatric patients is seen in patients who received a pre-emptive transplant or after short-term dialysis (<45 days). The poorest graft survival (52%) is in adult patients transplanted after long-term dialysis (>2.2 years). Kidneys from the youngest deceased donors have the poorest survival rates, although conversely, younger recipients tend to have improved renal transplant survival overall compared to older children.

33.2. Many children with long-term conditions (such as inflammatory bowel disease, the arthritides or connective tissue disorder, nephrotic syndrome, cystic fibrosis, or transplantation) have been taking long-term corticosteroids. When considering adverse drug reactions (ADRs) important issues to consider include:

A. 20% of patients will have a reduction in skeletal growth/final adult height – females being more significantly affected than males
B. 20% of patients develop Cushingoid features with long-term steroid use – but low-dose steroids are not associated with this risk
C. Children and young people have lower rates of mood and behaviour changes with steroid therapy than adults
D. 25% of patients have biochemical evidence of hypothalamic-pituitary axis (HPA) suppression and this predisposes them to viral infections
E. Half of all steroid-related deaths are due to infection and varicella zoster is the single commonest causative organism in patients who die from steroid-related sepsis

Answer: E.

Treatment with long-term steroids carries significant long-term health risks, and these are particularly important for children who have been exposed to steroids for long periods of time during their childhood. Up to 20% experience reductions in growth – males are more significantly affected than females and there is an average significant weight gain of 5%–10%. Children and young people seem more vulnerable to mood and behaviour side-effects than adults and steroid psychosis can be a particular problem in adolescents. Sixty per cent of patients on long-term steroids have biochemical evidence of HPA suppression and this makes them particularly vulnerable to infections. Varicella is the commonest cause of sepsis-related deaths and sepsis is the most serious of the described ADRs.

33.3. When considering the initiation of transition planning, which of the following is true?

A. It is sensible to plan this to coincide with the end of the young person’s time in full-time education
B. Transition planning is better delayed in patients with learning difficulties to aid their understanding of the process
C. Transition planning should begin between 11–12 years of age in all young people with a long-term condition likely to need treatment in adulthood
D. Transition planning should be started earlier in children with more severe conditions
E. It is best to involve adult clinicians in shared clinical care as early as possible in the transition process

Answer: C.

Transition planning should be initiated at around 12 years of age in all patients who are likely to have ongoing health needs in adulthood, regardless of disease severity, the presence of learning difficulties or even the patient’s willingness to consider transfer to another provider. The face-to-face consultation with adult colleagues and shared clinical decision-making is one of the final steps before full transfer to adult services.

33.4. Obesity is a growing problem in paediatrics and adolescence. When prescribing drugs for patients who are overweight which of the following is true?

A. When prescribing drugs on a dose per kilogram basis it is important that the actual weight for height is used when calculating drug dosages, even if the calculated dose exceeds the recommended adult dose
B. When prescribing drugs on a dose per kilogram basis, it is important that the optimal weight for height is used when calculating drug dosages and not to exceed the recommended adult dose
C. Adult drug dosages can safely be used in male and female children above 16 years since growth has stopped by then
D. Hydroxychloroquine can be prescribed using either optimal or actual body weight in adolescents who are clinically obese
E. Obesity in adolescents is generally defined to be present when the actual body weight is more than 30% greater than optimal body weight

Answer: B.

Many paediatric prescribing regimens use a dose per kilogram regimen to avoid overdosing. However, in obese young people (those in whom actual weight is >20% ideal weight) this can result in a risk of overdosing. Accordingly, ideal body weight rather than actual body weight should be used when calculating drug dosages. Centile charts can be used to calculate ideal body weight in growing children based on age and height. It should be noted that height and weight continue to increase through the late teenage years in boys, whereas in girls, both tend to stabilise around the age of 16 years. Whether or not the patient is obese, it is important to ensure that the actual dose prescribed does not exceed the standard adult dose.
33.5. A 19-year-old male presented to your hospital after a witnessed out-of-hospital cardiac arrest. He was previously fit and well but resuscitation was not successful and the clinical diagnosis was of sudden cardiac death (SCD). The family are seeking advice about the risks for the wider family; there are two surviving siblings, aged 16 and 12 years old. Which of the following is true:

A. The cause of death can be identified in 60% of cases once histopathology results are available
B. The siblings need to undergo cardiac screening
C. First-degree relatives should undergo ECG, echocardiogram, exercise tolerance test, Holter monitor, cardiac MR and adrenaline challenge
D. If the post mortem is normal, a primary arrhythmia syndrome is the most likely diagnosis. The majority of these are inherited in an autosomal dominant manner
E. It is important to diagnose hypertrophic cardiomyopathy (HCM) as this has genetic implications and treatment with propranolol modifies disease progression

Answer: D.

Sudden cardiac death in the young is a devastating event and generates significant familial anxiety. If post mortem examination is normal then inherited arrhythmia is the most likely diagnosis (such as long QT syndrome, Brugada syndrome). Genetic testing in the proband is helpful, but first-degree family members should also undergo detailed cardiological assessment including ajmaline challenge to exclude Brugada syndrome. The diagnostic yield is much higher if parents are included as well as siblings — extending the investigations to surviving family members increases the chances of reaching a definitive diagnosis to 40% even in cases where post mortem examination is normal. HCM could be diagnosed at post mortem examination and is relatively common, affecting 1 in 500 people. It too has autosomal dominant inheritance. Treatment with beta blockers reduces the incidence of sudden death but has not been shown to alter progression of hypertrophy. An implantable cardiac defibrillator ICD is considered the only effective strategy for prevention of arrhythmic SCD in patients with HCM.

Assessment of the older adult

7 Cognitive function
Montreal Cognitive Assessment
(see Ch. 31)
Assess for delirium
Assess mood

6 Vision
Visual acuity
Glasses worn/present
Cataract

5 Hearing
Wax
Hearing aid used

4 Erect and supine blood pressure
Postural hypotension, see opposite

3 Pulse
Atrial fibrillation

2 Hydration
Skin turgor
Oedema, including sacral oedema
Mucous membranes

1 Nutrition
Body mass index
(Height calculated from arm demispan or knee height to compensate for loss of vertebral height)
Recent weight loss, e.g. loose skin folds

Measurement of knee height
(see Ch. 22)

Full systems examination with particular attention to the above

8 Oral cavity
Dentition
Swallow assessment

9 Muscle
Wasting
Strength

10 Bladder and bowel
Faecal impaction
Prostate size/consistency in men
Palpable bladder

11 Skin
Pressure areas
Pattern of bruising (falls, non-accidental)

12 Joints
Deformity
Pain
Swelling
Range of movement

13 Feet
Ulcers
Onychogryphosis
Neuropathy

14 Gait and balance
Get up and go test (see opposite)
Walking aid used

**History**

**Approach**
- Find a quiet area free from external distractions
- Ensure the patient can hear
- Slow down the pace
- Carry out a full systematic enquiry

**Content**
- Establish the person’s goals and expectations of treatments
- Medication history, including adherence, recent changes to medications and any non-prescribed drugs or supplements
- Past medical history, even from many years previously
- Establish usual function – change in function is often a sign of illness
- Ask specifically about: mobility, continence, cognition, self-care

**Collateral**
- Obtain a collateral history from a suitable informant (relative, care-giver or family doctor)
- Ask about care-giver stress

**Social assessment**

**Home circumstances**
- Living alone, with another person or in a care home
  - Stairs, access to toilet, adequate heating

**Activities of daily living (ADL)**
- Tasks for which help is needed:
  - Basic ADL: bathing, dressing, walking
  - Extended ADL: shopping, cooking, housework

**Social support**
- Informal assistance: relatives, friends, neighbours
- Formal assistance: social care, home help, meals on wheels

**Examination – general points**

- Thorough and systematic
- Tailored to the patient’s stamina and ability to cooperate, may need to be performed in stages
- Includes cognitive function, gait, hearing and vision
- Initial assessment is screening rather than diagnostic; for example, screening visual acuity can be performed using different sizes of print in a newspaper
- Maintains safety; for example, ensure you have appropriate assistance before mobilising an unwell older adult for the first time
- Includes assessment of risk of future events; for example, assessing skin for risk of pressure sores, assessing gait and balance for risk of falls

**Cognitive screening**

- S sensitively, enquire about level of education and ability in reading and writing.
- Maximise cognitive abilities, ensure glasses are worn, hearing aids turned on.
- Screen for delirium using a validated tool such as 4-A test. If the person struggles with this test then more detailed direct testing may not be possible.
- Use a multidomain cognitive assessment validated for the language of the person being tested (e.g. Montreal Cognitive Assessment, see Ch. 31).
- Complement the cognitive assessment with collateral information, use a structured questionnaire such as the AD8.
- Change in cognition is important; look for results of any previous cognitive tests in medical records.

**Assessment for postural hypotension**

- Have the person supine and relaxed for at least 5 minutes.
- Measure blood pressure with manual sphygmomanometer.
- Keep the sphygmomanometer cuff on the person’s arm.
- Stand the person up rapidly but safely (in some cases lying to sitting measures may be needed).
- Check standing blood pressure immediately and then at 1, 2, 3 minutes.
- Ask about symptoms with each blood pressure check.
- A fall of >20 mmHg systolic or >10 mmHg diastolic defines postural hypotension, but important symptomatic drops may be seen with lesser falls in blood pressure.

**Get up and go test**

To assess gait and balance, ask the patient to stand up from a sitting position, walk 3m, turn and go back to the chair. This can be timed and usually takes less than 12 seconds. However, observed performance is more important than precise timing.
Demographic change has meant that older people now represent the core practice of medicine. A knowledge of the effects of ageing and the associated clinical problems is therefore essential for all clinicians. The older population is diverse; a substantial proportion of 90-year-olds enjoy an active healthy life, while some 70-year-olds are severely disabled by chronic disease. The terms ‘chronological’ and ‘biological’ ageing have been coined to describe this phenomenon. In the context of medical care, biological age is the more important factor to consider.

Geriatric medicine is concerned particularly with frailty – where physiological capacity is so reduced that even minor illness has serious consequences. Management in frailty differs from that in a robust younger adult in fundamental ways. Disability and multiple comorbidities can complicate both assessment and treatment and acute illness may present with non-specific symptoms. A broad knowledge of medicine is required, as disease in any, and often many, organ systems has to be managed at the same time. Finally, the person’s expectations and goals of treatment may differ from younger adults and these should be established as early as possible.

Older people are under-represented in clinical trials. Accordingly, there is often little high-quality evidence on which to base practice. However, some interventions have a compelling evidence base, such as the process of Comprehensive Geriatric Assessment.

### Demography

Improvements in health care, lifestyle and public health measures have resulted in prolonged life expectancy across the world. For example, in the UK, the total population has grown by 11% over the past 30 years, but the number of people aged over 65 years has grown by 24%, with the steepest rise in those aged over 80. In contrast, the working age population has remained relatively static. Similarly, the proportion of people aged over 65 in India has increased by 35.5%, which is almost twice the rate of growth of the general population. The rate of population ageing is much faster in developing countries and so there will be less time to adjust to its impact.

Thus, the old-age dependency ratio, which is the ratio of people of working age to people over retirement age, has substantially increased. Since young people support older members of the population both directly and indirectly through taxation and pension contributions, the consequences of this change are far-reaching. It is important to emphasise, however, that many older people also support the younger population, through the care of children and other older people.

Life expectancy gains are seen even in old age (Box 34.1); women aged 80 years can expect to live for a further 10 years. However, rates of disability and chronic illness rise sharply with ageing and have a major impact on health and social services. In the UK, the reported prevalence of a chronic illness or disability sufficient to restrict daily activities is around 25% in those aged 50–64, but 66% in men and 75% in women aged over 85.

### Functional anatomy and physiology

#### Biology of ageing

At a biological level, ageing can be defined as the progressive accumulation of random molecular defects that build up over the life course. Despite multiple repair and maintenance mechanisms, eventually these defects result in functional impairments of tissues and organs.

Genes that contribute to ageing profiles include those involved in regulation of DNA repair, telomere length and insulin signalling. However, genetic factors only account for around 25% of the variance in human lifespan with lifestyle and environmental factors more important determinants.

### Core concepts in older adults

#### Frailty, disability and multimorbidity

#### Frailty

Frailty is defined as the inability to withstand minor stresses because of reduced functional reserve in several organ systems. Thus, in frailty even a trivial illness may result in organ failure and death (Fig. 34.2). The term ‘frail’ has often been used rather vaguely, sometimes to justify a lack of adequate investigation and intervention in older people. Frailty research has substantially increased in the last decades and we now have a better understanding of the meaning and implications of frailty.
There are various complementary approaches to the assessment of frailty (Box 34.3). The cumulative deficit model counts the number of age-related symptoms, signs, diagnoses and test abnormalities. If this count is compared against a pre-defined list of issues, then a frailty index can be calculated. The phenotypic approach is based on a series of common features associated with poor outcomes, such as exhaustion and reduced strength. Finally, the syndromic approach recognises that patients with frailty tend to respond to disease in stereotyped ways. A list of presentations that are markers of underlying frailty was first described by Sir Bernard Isaacs in his text on ‘Geriatric Giants’. Formal phenotyping and frailty indexing are mostly used in research settings. In clinical practice, clinicians can often recognise frailty based on initial assessment. Frailty scales, such as that described by Rockwood, offer guidance and illustration to allow the categorisation of clinical frailty into an ordinal scale (Fig. 34.3).

Older people with frailty benefit from a clinical approach that addresses both the acute illness and their underlying loss of reserves. It may be possible to prevent further loss of function through early intervention. For example, a frail woman with myocardial infarction may benefit from cardiovascular secondary prevention medications but may benefit even further from an exercise programme that improves musculoskeletal function, balance and aerobic capacity. Establishing a patient’s level of frailty also helps inform decisions regarding further investigation, management and the need for rehabilitation.

### Disability

Disability is an umbrella term for describing loss of function that results from complex interactions between health, environmental and personal factors. The WHO International Classification of Functioning, Disability and Health (ICF) provides a framework for understanding this concept at the levels of basic body structure and function, activity limitations (previously called disability) and participation in society (previously called handicap) (Fig. 34.4). Care of the older adult should seek not only to cure or limit disease but also to minimise the resulting disability. Given the multifaceted nature of disability, this often requires a team approach with expertise in differing areas.

### Multimorbidity

Multimorbidity describes a state where multiple health conditions coexist in an individual. A related term is comorbidity which describes conditions that exist alongside a disease of interest. There is no consensus on the total number of conditions that should define multimorbidity and with increasing age, accumulation of chronic conditions is almost invariable. Regardless of the definition used, multimorbidity is a driver for future disability, hospitalisation and death. Related to multimorbidity is the concept of polypharmacy, where multiple medications are used to treat each chronic disease individually.

Traditional health-care systems are poorly equipped to manage multimorbidity. When each disease is dealt with by a separate team of specialists, this places a high burden on the patient and can lead to inefficiency.

It is important to understand the difference between frailty, disability and multimorbidity. These concepts frequently coexist, but they are distinct. Disability indicates established loss of function while frailty indicates increased vulnerability to loss of function. Disability may arise from a single pathological event (such as a stroke) in an otherwise robust individual. When frailty and disability coexist, function may deteriorate markedly even with minor illness, to the extent that the patient can no longer manage independently. Multimorbidity is also not equivalent to frailty or disability; it is possible to have several diagnoses without major impact on homeostatic reserve or function.
**Rehabilitation**

Rehabilitation aims to improve the ability of people of all ages to perform activities that are important to them. Rehabilitation is often needed in older adults for two reasons: acute illness can be associated with decline in functional ability and with increasing age comes increasing risk of chronic disabling conditions such as osteoarthritis or stroke.

**The rehabilitation process**

Rehabilitation is a holistic, problem-solving process focused on improving the patient’s physical, psychological and social function. It entails:

- **Assessment.** The nature and extent of the patient’s problems can be identified using the WHO ICF (see Fig. 34.4). Doctors tend to focus on health conditions and impairments but patients are often more concerned with daily activity and ability to participate in society. Specific assessment scales, such as the Barthel Index of basic activities of daily living (ADL) (Box 34.4) are useful to quantify function but additional assessment is needed to determine the underlying causes and interventions required.

- **Goal-setting.** Goals should be specific to the patient’s problems, should be realistic and agreed between the patient and the rehabilitation team.

- **Intervention.** This includes treatments needed to achieve goals and to maintain health and quality of life. Interventions may include hands-on treatment by therapists using a functional, task-oriented approach, education, training and psychological support. The emphasis on the type of intervention will be individualised, according to the patient’s goals and abilities.

- **Re-assessment.** There is ongoing re-evaluation of the patient’s function and progress towards the goals by the rehabilitation team, the patient and the care-giver. Interventions may be modified as a result.

**Multidisciplinary team working**

Effective rehabilitation requires a multidisciplinary team approach; core members of the team are described in Box 34.5. Others may also be involved as needed, such as audiometrists to correct hearing impairment, podiatrists for foot problems and orthotists where a prosthesis or splinting is required. Good communication and mutual respect are essential. Regular team meetings allow sharing of assessments, agreement on rehabilitation goals and interventions, evaluation of progress and planning for discharge. Rehabilitation is not when the doctor orders ‘physiotherapy’ or ‘a home visit’ and takes no further role.

**Rehabilitation outcomes**

There is evidence that rehabilitation improves functional outcomes and reduces mortality in older people following acute illness like stroke and hip fracture. These benefits accrue from complex multi-component interventions, but occupational therapy to improve personal ADLs and individualised exercise interventions have been shown to be effective in improving functional outcome in their own right.

---

**Investigation and management**

**Comprehensive Geriatric Assessment**

One of the most powerful tools in the management of older people is Comprehensive Geriatric Assessment (CGA) (Fig. 34.5). The term assessment is in fact a misnomer; CGA is not merely assessment, but a dynamic, iterative process of identifying and managing all factors affecting the health and well-being of an older person. The process should begin as soon as possible following acute illness or functional decline. The outcome should be a coordinated, goal-driven, management plan that not only addresses the acute presenting problems but also seeks to improve the patient’s overall health and function.
The CGA approach was pioneered by Dr Marjory Warren in the 1930s. Her comprehensive assessment and rehabilitation of supposedly incurable, bedridden older people revolutionised the approach of the medical profession to frailty and laid the foundations for the modern specialty of geriatric medicine. There is now excellent evidence from systematic reviews that CGA reduces death or deterioration and increases the chances of living independently at home. Current evidence suggests that the process works best when delivered by a dedicated multidisciplinary team on a specialist inpatient unit.

### Decisions about investigation and treatment

Accurate diagnosis is important at all ages but management plans in older adults need to be mindful of the implications of frailty, disability and multimorbidity. However, old age alone should not permit denying potentially useful treatments. Change in function should never be dismissed as due to age alone. For example, it would be wrong to supply a wheelchair to a patient struggling to mobilise, when simple tests would have revealed treatable osteoarthritis and angina. So how do clinicians decide when and how far to investigate?

**Does the patient want this investigation?**

Older people may have strong views about the extent of investigation and the treatment they wish to receive, and these should be sought from the outset. A key issue is to establish what the patient wants from investigation and treatment. Many older people do not desire prolongation of life; rather they aspire to maintain physical function, gain relief from symptoms and preserve the ability to live independently. It can be useful to proactively document the person’s wishes, particularly around the interventions that are acceptable to them, so that difficult decisions around ceilings of care do not have to be made in an emergency. There can be situations where a person is unable to sufficiently understand or communicate their circumstances to make informed decisions. Every effort should be made to maximise the patient’s ability to participate in decision-making and this may require input from other team members such as speech and language therapy. Family or care-givers may be able to give information on views previously expressed by the patient or on what they believe the patient would have wanted under the current circumstances. However, families should never be made to feel responsible for difficult decisions. Advance directives or ‘living wills’ allow people to document their views and are used if they no longer are able to make or communicate these decisions. Advance directives and family wishes cannot authorise a doctor to do anything that, in their professional opinion, is not clinically appropriate.

**Will the investigation be feasible?**

Does this patient have the capacity to tolerate the proposed investigation? For example, do they have the aerobic capacity to undergo bronchoscopy? Will delirium prevent them from remaining sufficiently still to allow magnetic resonance imaging (MRI) scanning of the brain? Increasing frailty, disability and comorbidity make it less likely a patient will be able to withstand an invasive intervention.

**Will the investigation alter management?**

Would the patient be fit for, or benefit from, the treatment that would be indicated if investigation proved positive? Again, frailty, disability and comorbidity are more important than age itself in determining this. When a patient with severe heart failure and a previous disabling stroke presents with a suspected cancer on chest X-ray, detailed investigation and staging may not be appropriate if they are not fit for surgery, radical radiotherapy or chemotherapy. On the other hand, if the same patient presented with dysphagia, investigation of the cause would be important, as they might be able to tolerate endoscopic treatment to palliate an obstructing oesophageal lesion and allow resumption of oral diet.

**Will management benefit the patient?**

It is important to consider whether interventions that might be considered as standard-of-care for younger people are likely to be beneficial in older people living with frailty. For example, while guidelines may recommend tight glycaemic control in diabetes mellitus, such treatment may not accord with the wishes of a patient in a care home who finds regular blood tests distressing, or who is more worried about immediate hypoglycaemia than future vascular complications.

### Presenting problems in geriatric medicine

#### Characteristics of presenting problems in old age

The traditional single-organ, single-disease-based paradigm is rarely helpful in older people. Most presentations are multifactorial, with a social and environmental aspect, and there is rarely a single unifying diagnosis. The diagnostic formulation is more commonly a list of problems, some acute and some chronic. There are certain features of illness presentation that are particular to older patients.

**Late presentation**

Many people (of all ages) accept ill health as a consequence of ageing and may tolerate symptoms for lengthy periods before seeking medical advice. Comorbidities may also contribute to late presentation. For example, in a patient whose mobility is limited by stroke, angina may only present when coronary artery disease is advanced, as the patient has been unable to exercise sufficiently to cause symptoms at an earlier stage.

**Atypical presentation**

The classical presentations of diseases are rarely seen in frailty. Infection may present with delirium and no clinical pointers to the organ system affected. Myocardial infarction may present as weakness and fatigue, without chest pain or dyspnoea. The reasons for these atypical presentations are not always easy to establish. Perception of pain is altered, and the pyretic response is blunted in old age. Cognitive impairment may limit the patient’s ability to give a history of classical symptoms.

**Acute illness and changes in function**

A change in functional ability is a common presentation of illness in frailty. Often labels such as ‘failure to cope’, and ‘off feet’ are used, but these
are not diagnoses, and should not prevent a comprehensive assessment for underlying precipitants. It is vital to establish the person’s usual level of functioning and the chronicity of any change. Collateral information from a relative or care-giver (by telephone if necessary) can be useful.

**Multiple pathology**

Presentations in older patients have diverse differential diagnosis, and various contributory problems, both acute and chronic, can coexist. For example, a patient may have recurrent falls because of osteoarthritis of the knees, drug-induced postural hypotension and poor vision from cataracts. All these factors must be addressed to prevent further falls.

**Approach to presenting problems in old age**

For the sake of clarity, the common presenting problems are described individually but, in reality, older patients often present with several presentations at the same time. Syndromes such as falls, or incontinence represent a final common pathway that is the result of a variety of insults. For most presenting problems in old age the clinician has to search for and treat any acute illness as well as identifying and reversing predisposing risk factors. The initial approach to assessment is often less focused than would be typical in a younger, robust patient (Box 34.6).

**Falls and collapse**

A commonly used definition describes a fall as an unexpected event in which the person comes to rest on the ground without known loss of consciousness. Around 30% of people over 65 years of age fall each year and this figure rises to more than 40% in those aged over 80.

Important aspects in the assessment of falls include an assessment of the mechanism, risk factors and consequences.

**Mechanism**

Falls are one of the classic presentations of acute illness in frailty. The reduced reserves in older people’s neurological function mean that they are less able to maintain their balance when challenged by an acute illness. The history may give a clear account of an accident, for example a trip on uneven ground. However, a proportion of older people who ‘fall’ have, in fact, had a syncopal episode. A collateral falls history from a witness is crucial as people who lose consciousness do not always remember having done so. As differentiating syncopal and non-syncopal falls is challenging, all patients who fall should have a 12-lead electrocardiogram and assessment for postural hypotension (see p. 1297).

**Risk factors**

Risk factors for falls should be considered in the history and examination (Box 34.7). If problems are identified with muscle strength, balance or vision, these should be investigated and treated as needed. Careful assessment of the patient’s gait may provide important clues to an underlying diagnosis (Box 34.8).

**Management**

Older adults who have fallen more than once in the past year and those who are unsteady during a ‘get up and go’ test (see p. 1297) require further assessment and may benefit from multidisciplinary intervention. Evidence-based interventions to prevent or reduce recurrent falls involve a multifactorial, multidisciplinary approach (Box 34.9). People at low or moderate risk of falls benefit most from balance and strength training delivered by physiotherapists or other suitably trained practitioners. An assessment of the patient’s home environment for hazards should be undertaken by an occupational therapist, who may also provide personal alarms so that the person can summon help, should they fall again. A medication review is required, rationalising medications that may be contributing to sedation, syncope or postural hypotension.

Calculation of fracture risk using tools such as FRAX or QFracture should be performed and dual X-ray absorptiometry (DXA) bone density scanning considered in patients with a 10-year risk of major osteoporotic fracture of more than 10%. If osteoporosis is diagnosed, specific drug therapy may be considered after informing the patient what their absolute risk of a fracture is over the subsequent 5 years with and without treatment. In the frailtest patients, such as those in institutional care, calcium and vitamin D₃ supplements have been shown to reduce both falls and fractures.

**Dizziness**

Dizziness is very common, affecting at least 30% of those aged over 65 years in community surveys. It can be disabling in its own right and is also a risk factor for falls and functional decline.

The management of dizzy spells is complicated by the difficulty that patients have in describing the symptoms. Important questions in the history include establishing timing and whether it is an acute event (suggesting stroke) or a more chronic problem (such as a space-occupying lesion); whether continuous (for example labyrinthitis) or episodic (for example benign positional paroxysmal vertigo) and any provoking or relieving factors (for example the effect of change in posture). There may be a predominant symptom complex (although more than one of these may be present).
**34.9 Evidence-based interventions to reduce the risk of falls and fractures**

- Exercise (should include components of lower limb strength and balance training):
  - Multimodal group exercise and Tai Chi are both effective
- Calcium and vitamin D supplementation:
  - Main evidence of effectiveness for patients in institutional care
- Home environment assessment and modification
- Medication review:
  - Particularly medications with central actions such as hypnotics but also those with anticholinergic and hypotensive actions
- Cataract surgery:
  - Effective if first cataract
  - Other vision interventions ineffective and may increase falls risk
- Anti-slip shoes:
  - Effective only in icy conditions
- Cardiac pacemaker for carotid sinus hypersensitivity

- **Pre-syncope, light-headedness,** impending faint. Suggestive of reduced cerebral perfusion. While structural cardiac disease (aortic stenosis) and arrhythmia must be considered, autonomic disorders such as postural hypotension are the most common cause. Regardless of cause, antihypertensive medications may exacerbate symptoms and deprescribing may help.

- **Vertigo,** an illusion of movement. Suggestive of (peripheral) labyrinthine or (central) brainstem disease. In older patients this is most commonly due to peripheral causes, but if any brainstem symptoms or signs are present, MRI of the brain is required to exclude a central lesion.

- **Dizziness,** unsteadiness, off balance, veering to one side. Suggestive of joint or neurological disease.

- **Psychological anxiety** and hyperventilation can be experienced as dizziness, or can complicate dizziness from other causes.

As with many conditions of older age, dizziness is often multifactorial. For example, a patient may have an acute labyrinthitis in the context of small-vessel cerebrovascular disease and peripheral neuropathy. A multifaceted approach is needed and making small improvements in each contributing problem can have a large effect on symptoms and function.

**Confusion (dementia and delirium)**

### Dementia

Dementia is a syndrome characterised by progressive loss of function across multiple cognitive domains (executive function, language, memory etc.). The cognitive deficits should be sufficient to cause problems in everyday activities. Where a person has cognitive impairment but no functional limitation this is often termed mild cognitive impairment. Further details on the assessment and management of dementia are available in Chapter 31.

A common clinical problem is trying to establish whether an older adult presenting with confusion has pre-existing, and potentially undiagnosed cognitive decline, or a more acute change that may suggest a delirium. To complicate the assessment, dementia and delirium commonly coexist. Cognitive screening of the patient can provide useful information and is described in Chapter 31. However, direct assessment of the patient may not always be possible, particularly if the person is medically unwell. Collateral information from someone that knows the person well, often termed an informant, can be useful. Figure 34.6 suggests a short, structured approach to the informant interview to assess for pre-existing cognitive disorders.

### Delirium

Delirium is a syndrome characterised by acute cognitive impairment, precipitated by an insult such as illness or surgery. Delirium is common, affecting around 25% of all hospital inpatients; 50% following hip fracture and 75% in intensive care. Delirium is associated with poor outcomes, including increased length of hospital stay, institutionalisation and mortality. Although traditionally considered a transient phenomenon, longer-lasting effects of delirium are described. In particular, delirium is a powerful risk factor for subsequent dementia and there is considerable overlap between ‘persistent delirium’ and dementia. The most important risk factors for delirium are frailty, dementia and a previous history of delirium. Other modifiable and non-modifiable risk factors are shown in (Box 34.10).

**Presentation**

Delirium presents as an acute change (hours to days) in cognition that often fluctuates over time. Collateral information is crucial to assess whether impaired cognition in the context of illness represents an acute change (delirium) or is a more chronic phenomenon (more likely dementia). The defining neuropsychological feature of delirium is a deficit in attention, although this can be accompanied by problems in other cognitive domains. Based on psychomotor patterns, subtypes of delirium are described. Patients with hyperactive delirium are often agitated and restless, whereas hypoactive delirium can present as lethargy and sedation. A mixed picture with periods of hyper- and hypoactivity is common. Hyperactive delirium is more common in frailty and can be easily missed unless specifically looked for.

**Clinical assessment**

In order to manage delirium effectively, the first step is to make a diagnosis. Screening tools such as the 4AT (Box 34.11) can be used to detect delirium and differentiate it from dementia and these should be applied to all older patients admitted to hospital. Once a diagnosis of delirium has been established, attempts should be made to identify reversible precipitating factors, especially acute illness. An accurate drug and alcohol history is required with a focus on any drugs recently started or stopped. Full physical assessment may be difficult, especially in hyperactive delirium if the person resists examination. Assessment for localising neurological signs and stigmata of head injury are essential as these would suggest the need for neuroimaging.

**Management**

The best management of delirium is to prevent it happening. The landmark studies of the Hospital Elder Life Program (HELP) demonstrated that a package of non-pharmacological interventions can reduce the incidence of delirium and its severity (see Box 34.10).

Once a diagnosis of delirium is established, the priority is to treat the underlying precipitating factors, recognising that these may be multiple. Life-threatening causes should be assessed for immediately, including sepsis, drug and alcohol intoxication or withdrawal, hypoglycaemia and other metabolic disorders. This should be followed by a systematic
Fig. 34.6 Eight-item informant interview to differentiate ageing and dementia (AD8). The AD8 is a screening test for the early cognitive changes that are common to many forms of dementia (Alzheimer’s disease, frontotemporal, vascular dementia). The test is best used as part of an interview with an informant, e.g., spouse, care-giver. A score of 2 or more ‘Yes’ answers suggests that a cognitive syndrome is likely. From Galvin JE, et al. The AD8: A brief informant interview to detect dementia. Neurology 2005; 65:559–564. Copyright © 2005 Washington University, St Louis, Missouri. All Rights Reserved.

### 34.11 How to make a diagnosis of delirium: the 4A Test (4AT)

#### 1 Alertness

This includes patients who may be markedly drowsy (e.g., difficult to rouse and/or obviously sleepy during assessment) or agitated/hyperactive. Observe the patient. If asleep, attempt to wake with speech or gentle touch on shoulder. Ask the patient to state their name and address to assist rating:

- Normal (fully alert and not agitated, throughout assessment) 0
- Mild sleepiness for <10 secs after waking, then normal 0

#### 2 Four-question abbreviated mental test (AMT4)

Ask the patient their age, date of birth, the place where they are (name of the hospital or building), the current year:

- No mistakes 0
- 1 mistake 1
- ≥2 mistakes/untestable 2

#### 3 Attention

Say to the patient: ‘Please tell me the months of the year in backwards order, starting at December.’ To assist initial understanding, one prompt of ‘What is the month before December?’ is permitted:

- Achieves ≥7 months correctly 0
- Starts but scores <7 months/refuses to start 1
- Untestable (cannot start because unwell, drowsy, inattentive) 2

#### 4 Acute change or fluctuating course

Evidence of significant change or fluctuation in: alertness, cognition, other mental function (e.g., paranoia, hallucinations) arising over the last 2 weeks and still evident in last 24 hrs:

- No 0
- Yes 4

**Total 4AT score (maximum possible score 12)**

- ≥10: delirium + cognitive impairment
- 1–9: possible cognitive impairment
- 0: delirium or severe cognitive impairment unlikely (but delirium still possible if information in 4 incomplete)

---

**Bladder health**

Urinary incontinence is defined as the involuntary loss of urine. It occurs in all age groups but is especially common in older age and frailty, with up to 80% of care-home residents being incontinent of urine. The initial assessment should seek to identify and address contributory factors and some of these may be easily remedied, for example infection,
Urinary incontinence

Active case finding

Address contributory factors:
- UTI
- Severe constipation
- Diuretics
- Hyperkalaemia
- Hypercalcaemia
- Restricted mobility

If still incontinent:
- Establish the pattern of urinary loss (use a three-day diary)
- Measure residual urine volume (by ultrasound)
- Assess for vaginal prolapse and atrophic vaginitis (women)
- Assess prostate by rectal examination (men)

Life style modification for all incontinence:
- Weight loss if obese
- Reduce caffeine consumption
- Smoking cessation
- Regular planned toileting (prompted toileting in dementia)

Urgency incontinence more than one continence issue may be present, most commonly urgency and stress in females and overflow and urgency in males.

Bowel health

Both constipation and faecal incontinence are common in older age and often coexist. Problems with bowel habit are often multifactorial and may result from cognitive factors, local bowel factors and external factors such as immobility. Assessment should include enquiring about diet, medication, previous surgery and lifelong bowel habit. The examination should include an anorectal assessment looking for prolapse, anal tone and faecal loading.

In patients with severe stroke disease or dementia, treatment may be difficult as cortical inhibitory signals are lost. A timed/prompted toileting programme may help.

Infection in the older adult

Infection is one of the commonest reasons for older adults to seek medical attention. All the considerations around disease in older age and frailty that have been discussed in this chapter remain pertinent in relation to infection – non-specific presentations, challenges of comorbidity, competing risks and benefits of interventions. In fact, infection could be considered an exemplar of the need for an adapted management strategy in older age.

Ageing and the immune system

Older adults, particular those living with frailty, face an increased risk and severity of infection. Although absolute numbers of immune cells do not change substantially with age, immune function decreases leading to less efficient responses of both the innate and adaptive immune systems, a phenomenon which is sometimes referred to as immunosenescence. Age-related changes in anatomy and physiology also occur that predispose to infection in certain sites. For example, in the respiratory system, blunting of cough reflex, impaired mucociliary clearance and decreased respiratory muscle strength with subsequent hypoventilation, increase the risk of pulmonary infection. Age-related changes in bladder function and thinning of the skin may partly explain the high prevalence of infection in these sites with older age. Factors that are common in older adults but not part of biological ageing are also important. These include, multiple morbidty, polypharmacy including use of antibiotics and immunosuppressants, and environmental exposures to pathogens.

Assessment

The diagnosis of infection in older age is challenging as symptoms and signs are often atypical and non-specific. Frailty syndromes of delirium and functional decline are common while ‘classical’ features of the disease such as pyrexia may be absent. Older adults have a lower baseline temperature and blunted or absent fever response to infection. Thus, a core temperature of greater than 38°C is likely to be indicative of important disease.

Unfortunately, the temperature response is non-specific in older adults and non-infective causes such as myocardial infarction and deep vein thrombosis need to be considered. The commonest infections seen in older age are respiratory, urinary and skin. However, with frailty, atypical infections and infections in atypical sites are often seen. Thus, the assessment of the unwell older adult always needs to consider infection and physical examination needs to be comprehensive including pressure areas, the oral cavity and intravenous cannulation sites. Consideration of the patient’s environment may offer clues to the underlying pathogen. The patient from a care home or who has had a prolonged hospital admission will be at risk from differing causative pathogens to the robust community-dwelling older adult.

Management

Treating infection in the older adult poses further challenges. The pharmacokinetics and pharmacodynamics of antibiotics change with ageing and older adults are at greater risk of adverse drug reactions. Given the
difficulty of making an initial diagnosis, the use of empirical broad-spectrum antibiotics may seem intuitive, but this approach is strongly discouraged not least due to the risks of *Clostridioides difficile* infection and promoting antibiotic-resistant strains. If the patient is not septic or rapidly deteriorating there should be time for investigations, including relevant cultures, before initiating antibiotic therapy. In liaison with the microbiology laboratory the prescribed therapy can be rationalised as results become available.

The adage ‘prevention is better than cure’ is particularly relevant in older age. Vaccination programmes for seasonal influenza, pneumococcal and herpes zoster can all reduce incidence, severity or complications from the relevant infections. Health-care associated infection is a particular concern in frailty and all staff working with frail older adults need to be mindful of infection control policies including meticulous hand washing between patient encounters. Without these measures, hospital ward and institutional care settings are at risk of outbreaks of diseases such as norovirus, scabies, methicillin-resistant *Staphylococcus aureus* and more recently COVID-19 (Box 34.12).

**Prescribing and deprescribing**

The multimorbidity that accompanies ageing often leads to polypharmacy (Box 34.13 and see Box 2.23). This has been defined as the use of four or more drugs, and is associated with adverse outcomes including falls, hospitalisation and increased risk of death. While some of these outcomes are caused by drug–drug interactions and adverse effects, others are due to the underlying problems for which the drugs were prescribed in the first place.

An important component of any older adult assessment is a critical review of medications. This group can be the victim of well-intentioned, but ultimately harmful, prescribing cascades where new medications are introduced to combat effects of other medications and these new medications in turn have adverse effects that result in further prescribing. Of course, for many older people, taking multiple drugs is entirely appropriate, as such therapy is required to treat multiple diseases. Getting the right balance between over- and undertreatment is a dynamic process and requires frequent, careful exploration of the person’s treatment goals.

**Adverse drug reactions**

The more drugs that are taken, the greater the risk of an adverse drug reaction (ADR) (Box 34.14). ADRs are the cause of around 5% of all hospital admissions but account for up to 20% of admissions in those aged over 65. The risks associated with polypharmacy are compounded by age-related changes in pharmacodynamic and pharmacokinetic factors as described in Chapter 2. Older people are especially sensitive to drugs that can cause postural hypotension or volume depletion and centrally acting drugs can often cause or exacerbate cognitive syndromes. However, the clinical presentations of ADRs are diverse, so for any presenting problem in old age the possibility that the patient’s medication is a contributory factor should always be considered. Prescribers must also be mindful of the burden of taking medications at various times, with need for monitoring, lifestyle restrictions and associated expense. It is perhaps not surprising that non-adherence to drug therapy rises with the number of drugs prescribed.

**Appropriate prescribing and deprescribing**

The key to appropriate prescribing is first to ensure that medications are started only for reasons that accord with the patient’s goals and wishes. Thoughtless adherence to specialist guidelines quickly leads to polypharmacy that may be inappropriate. Some medications (such as chronic use of non-steroidal anti-inflammatory medications) are best avoided in older people because of the high risk of ADR. Other medications, such oral bisphosphonates, lack evidence of efficacy in very old people, who may not live long enough to derive benefit.

Deprescribing is as important as prescribing in older people. Regular review of medications should be undertaken to ensure that medications are still required, to establish that they are still working, to check that they are not causing side-effects, and to ascertain whether the patient is actually taking them. The patient or care-giver should be asked to bring all
medication for review rather than the doctor relying on previous records. Such reviews should take place regularly, not just at a point of crisis such as after a fall or on hospital admission. Deprescribing of medications that have been taken for years needs to be done in a controlled manner, with dose reduction to ensure that rebound symptoms or withdrawal effects do not occur.

There are tools to assist with rational prescribing choices in older adults. The American Geriatrics Society Beers’s criteria is an expert generated list of medications that should be avoided or used with caution in old age. A similar European initiative is STOPP (Screening Tool of Older Person’s Prescriptions) and START (Screening Tool to Alert to Right Treatment), which recognises that good prescribing in old age should ensure effective treatments are prioritised as well as discontinuing those medications that may be of limited benefit or potential harm.

### Other problems in old age

A vast range of other presenting problems in older people present to many medical specialties. End-of-life care is an important facet of clinical practice in old age and the general principles of this are discussed in Chapter 8. Relevant sections in other chapters are shown in Box 34.15.

Within each chapter, ‘In Old Age’ boxes highlight the areas in which presentation or management differs from that in younger individuals.

Multiple Choice Questions

34.1. An 85-year-old retired professor attends the clinic. His family describe 2 years of worsening memory. He repeats stories, is no longer able to pay bills and becomes lost when going to the shops. On examination he is alert and chatty, with no localising neurology. You perform a Montreal Cognitive Assessment and he scores 27/30 (normal range 26–30). What is the most likely diagnosis?

A. Mild cognitive impairment  
B. Dementia  
C. Delirium  
D. Depressive pseudo-dementia  
E. Subdural haematoma

Answer: A.

There is a clear description of progressive cognitive decline causing functional problems, these are the main features of dementia. His ‘normal’ cognitive score does not alter the likely diagnosis; the test used is a screening test and false negatives are often seen in highly educated people. Mild cognitive impairment implies cognitive change with no functional consequence. The presentation and symptom duration would not be in keeping with delirium or pseudo-dementia. Subdural haematoma is unlikely with no neurological signs.

34.2. A 98-year-old woman is admitted to hospital with pneumonia that presents as delirium, falls and new incontinence in the context of complex morbidity and polypharmacy. Which of these models of care is likely to give the best outcomes?

A. Admission to dedicated geriatric medicine ward with multidisciplinary team  
B. Admission to critical care ward with multidisciplinary team  
C. Admission to respiratory ward with consult from geriatric medicine  
D. Discharge home with outpatient follow-up  
E. Discharge to care home

Answer: A.

This woman has evidence of frailty and will benefit from Comprehensive Geriatric Assessment (CGA). Evidence suggests that CGA works best when delivered in a dedicated space with a multidisciplinary team. Other models of CGA such as peripatetic or outpatient clinic consultations are less effective. It is unlikely she would tolerate or benefit from organ support and so critical care is not appropriate. She is too unwell to immediately discharge home.

34.3. A 99-year-old woman presents with an acute coronary syndrome in the context of frailty. She makes a good recovery and echocardiogram suggests preserved left ventricular function, but she continues to experience angina symptoms on exertion. Random blood glucose is high (11.0 mmol/L, 198 mg/dL) and blood pressure is 172/88 mmHg. She wishes to avoid taking tablets. Which of these medications would you want to prioritise?

A. Insulin  
B. ACE-inhibitor  
C. Statin

Answer: E. Amlodipine

In an older adult with frailty, prescribing decisions may not always follow guideline recommendations for younger patients. A statin and ACE-inhibitor have prognostic benefits that may not be realised in this patient. She wants to limit her medication burden and amlodipine offers antianginal and antihypertensive effects. Alpha-blockers offer only antihypertensive action and are poorly tolerated in older adults. A diagnosis of diabetes mellitus has not been made and so there is no role for insulin.

34.4. An 88-year-old man slips on ice and fractures his distal right radius. He is right-hand dominant. He is usually mobile with a stick. He requires joint immobilisation and is admitted for a period of geriatric assessment. On assessment of activity of daily living, he struggles to dress due to his fracture. The occupational therapist gives him a tool to assist with buttons and zips. At which level of the World Health Organization International Classification of Function (WHO ICF) is this intervention directed?

A. Activity  
B. Disability  
C. Handicap  
D. Impairment  
E. Quality of life

Answer: A.

In the WHO ICF, Activity (A) describes the execution of a task or action by an individual. The term disability (B) is now taken as a general term for impairments, activity limitations and participation restrictions. The term handicap (C) is no longer used and has been replaced by societal participation. Impairment (D) refers to problems in body structure and function. Quality of life is not part of the WHO ICF.

34.5. A usually well 84-year-old man presents with new-onset urinary incontinence. He has little past medical history but has been taking non-steroidal anti-inflammatories for worsening back pains over the last weeks. On initial physiotherapy assessment he is found to have difficulty walking. What is the most appropriate management of his incontinence?

A. Further physiotherapy to improve back pain and mobility  
B. Pelvic floor muscle training  
C. Prescription of alpha-blockers for presumed prostatic hypertrophy  
D. MRI scanning of spinal cord  
E. Empirical antibiotics pending urine culture

Answer: D.

New-onset incontinence should not be accepted as a natural consequence of ageing. In this case the backpain and change in mobility are suggestive of potential spinal cord compression and demand immediate imaging. Physiotherapy, screening for urinary tract infection and assessing for prostatic hypertrophy could all be useful once spinal cord compression is excluded. Pelvic floor training has greatest benefit in women with stress incontinence.

Notes on the international system of units (SI units)

Système International (SI) units are a specific subset of the metre–kilogram–second system of units and were agreed on as the everyday currency for commercial and scientific work in 1960, following a series of international conferences organised by the International Bureau of Weights and Measures. SI units have been adopted widely in clinical laboratories but non-SI units are still used in many countries. For that reason, values in both units are given for common measurements throughout this textbook and commonly used non-SI units are shown in this chapter. The SI unit system is, however, recommended.

Examples of basic SI units

Examples of decimal multiples and submultiples of SI units

In most of this textbook, the litre (L) is used as the unit of volume in laboratory work.

Exceptions to the use of SI units

By convention, blood pressure is excluded from the SI unit system and is measured in mmHg (millimetres of mercury) rather than pascals.

Mass concentrations such as g/L and µg/L are used in preference to molar concentrations for all protein measurements and for substances that do not have a sufficiently well defined composition.

Some enzymes and hormones are measured by ‘bioassay’, in which the activity in the sample is compared with the activity (rather than the mass) of a standard sample that is provided from a central source. For these assays, results are given in standardised ‘units’ (U/L), or ‘international units’ (IU/L), which depend on the activity in the standard sample and may not be readily converted to mass units.

Laboratory reference ranges in adults

Reference ranges are largely those used in the Departments of Clinical Biochemistry and Haematology, Lothian Health University Hospitals Division, Edinburgh, UK. Values are shown in both SI units and, where appropriate, non-SI units. Many reference ranges vary between laboratories, depending on the assay method used and on other factors; this is especially the case for enzyme assays. Wherever possible an internationally agreed standard reference material is used to calibrate assays and reference ranges and assay nomenclature are standardised between laboratories. The origin of reference ranges and the interpretation of ‘abnormal’ results are discussed on page 3. No details are given here of the collection requirements, which may be critical to obtaining a meaningful result. Unless otherwise stated, reference ranges shown apply to adults; values in children may be different.

Many analytes can be measured in either serum (the supernatant of clotted blood) or plasma (the supernatant of anticoagulated blood). A specific requirement for one or the other may depend on a kit manufacturer’s recommendations. In other instances, the distinction is critical. An example is fibrinogen, where plasma is required, since fibrinogen is largely absent from serum. In contrast, serum is required for electrophoresis to detect paraproteins because fibrinogen migrates as a discrete band in the zone of interest.

### 35.1 Urea and electrolytes in venous blood

</tbody>
</table>

**Notes**

1. A number of hormones are unstable and collection details are critical to obtaining a meaningful result. Refer to local laboratory handbook.
2. Values in the table are only a guideline; hormone levels can often be meaningfully understood only in relation to factors such as gender, age, time of day, pubertal status, stage of the menstrual cycle, pregnancy and menopausal status.
3. Vitamin D levels vary seasonally in many parts of the world, with levels being higher in the summer months in most people due to increased exposure to solar UV-B rays.
4. Reference ranges are usually dependent on the method used for analysis and frequently differ between laboratories. Non-SI units also differ; those shown here are amongst those most widely used. Readers are encouraged to consult their local laboratory for non-SI units for individual analytes and their respective reference ranges.

(RU = relative units. Relative units are used since at the present time there is no agreed international standard for the measurement of FGF-23.)

The levels of many analytes in blood vary due to the physiological changes that occur during growth and adolescence. Hospital laboratories may provide reference ranges that are age-adjusted or based on pubertal stage but this is not always the case. It is therefore important for the doctor requesting these tests to understand the impact of age and puberty on interpretation of the results. For example, a creatinine of 70 μmol/L (0.79 mg/dL) is perfectly normal for the majority of adults but may indicate significant renal impairment in a child. Reference ranges for hormone results are described according to the Tanner stages of puberty (see Fig. 33.5).

Laboratory reference ranges in pregnancy

The levels of many analytes in blood vary during pregnancy, when many hormonal and metabolic changes occur. The standard adult reference ranges may therefore not be appropriate and it is important for the clinician reviewing the results to be aware of this to enable appropriate interpretation and patient management.

### 35.10 Analytes that may be significantly affected by pregnancy*

Incidental pancreatic mass, 856
‘Incidentalomas,’ 651b
Inclusion body myositis, 1061–1062
Incontinence
continual, 608
overow, 608, 1148
stress, 608
urge, 608, 1148
urinary, 567, 608–609
older people, 608b, 1305–1306, 1306f
Incremental cost-effectiveness ratio (ICER), 28
Indirect antiglobulin tests, 957f
Indometacin, 1010b
for paroxysmal headache prevention, 1151
for pericarditis, 476
for persistent ductus arteriosus, 468–469
Inductively coupled plasma/mass
spectroscopy, 616b
Infection(s), 261, 939
in adolescence, 278, 279b
agents of, 98–100, 98b
bacterial, 299–319
after HSCT, 946b
chlamydial, 319, 319b
gastrointestinal, 309–312
with neurological involvement, 314
respiratory, 312–314
rickettsial, 316–319, 317b
of skin, 1088–1091
soft tissues and bones, 299–303
systemic, 303–309
caused by helminths, 332–342, 332b
central venous catheter, 271
chain of, 98f
chlamydial, 379–380
treatment of, 380b
urethritis, 372
clinical examination of, 262–264, 262f
common infecting organisms, 114b
constitutive barriers to, 61
control, 108–112, 109b
cytomegalovirus, 282b, 286
after HSCT, 946b
clinical features of, 286
encephalitis, 362
investigations of, 286
management of, 286
polyradiculitis, 363
in pregnancy, 280b
denition of, 98
deliberate release, 108

Infection(s) (Continued)
diabetes mellitus and, 747b
emerging and re-emerging disease, 107,
107f
endemic disease, 106–107
epidemiology of, 106–108
Epstein-Barr virus, 282b, 285–286
clinical features of, 285
complications of, 285, 285b
investigations of, 285
management of, 286
Escherichia coli, 310–311
entero-aggregative, 310
enterohaemorrhagic, 310–311
entero-invasive, 310
enteropathogenic, 310
verocytotoxigenic, 311f
fungal, 342–347, 343f
after HSCT, 946b
skin, 1092–1093, 1092f
subcutaneous, 344
supercial, 343–344
systemic, 344–347
gastrointestinal tract
function of, 793, 795b
oral cancer, 805
test of, 793
geographical and temporal patterns of,
106–108
history-taking in, 263b
HIV/AIDS, 349, 355
antiretroviral therapy for, 366–368, 366b
asymptomatic, 355, 356f
CD4 counts in, 354–355
chemoprophylaxis for, 365–366
clinical examination of, 350–352
clinical manifestations of, 355
diagnosis of, 354, 354b, 355b
epidemiology of, 352
global and regional epidemics of, 352b
immunisation for, 366–367
immunology of, 352–354
investigations of, 354–355, 355b
life cycle of, 353f
liver and, 891
liver blood tests in, abnormal, 891b
modes of transmission of, 352, 352b,
353b
musculoskeletal manifestations of,
1026b
in old age, 368b
pregnancy and, 1274
presenting problems of, 355–365, 356b
prevention of, 365, 368b–369b
primary, 355, 355b
pruritus and, 1073b
staging classications of, 351b
tuberculosis and, 524
viral load in, 354–355
virology of, 352–354
host-pathogen interaction of, 101–102
incubation periods of, 108b
investigation of, 102–106, 103b
culture, 104–105
direct detection of pathogens, 103–104
joints, 1025–1027
in old age, 1025b
of liver, 884–892
liver transplantation and, 912
microbiological sampling, 103b
mycobacterial, 314–316
nematode, 278b
intestinal, 332–335
tissue-dwelling, 335–337, 335b
zoonotic, 337–338
in non-immune haemolytic anaemia, 959
normal microbial ora, 100–101, 101f
of oesophagitis, 807
outbreaks of, 109–111, 111b
reporting, 111b
terminology, 116b
parvovirus B19, 280–281
clinical features of, 280–281, 281b, 281f
diagnosis of, 281
management of, 281
in pregnancy, 280b
periods of infectivity, 108b
in pregnancy, 279, 280b
presenting problems in, 264–279
prevention, 108–112, 109b
protozoal, 319–332
gastrointestinal, 330–332
leishmaniasis, 326–330

Infection(s) (Continued)
systemic, 319–326
recurrent, 70–71
reservoirs of, 107–108
animal, 107–108
environmental, 108
human, 107
respiratory, 512–528, 512b
in old age, 512b
pneumonia, 512–518
pregnancy and, 1271
tuberculosis (TB), 518–525
upper respiratory tract infection, 512
rubella
clinical features of, 279
congenital malformation and, 281b
diagnosis of, 279–280
in pregnancy, 280b
prevention of, 280
sexually transmitted, 369–370, 371b
in children, 372
contact tracing for, 376–377
management goals of, 376b
men who have sex with men, 371b
during pregnancy, 372
presenting problems, 372–375
prevention of, 376–377, 376b
those at particular risk, 371b
viral, 380–383
skin, 1088–1094
bacterial, 1088–1091
fungal, 1092–1093, 1092f
mycobacterial, 1090
tropical, 277–278, 278b, 279f
viral, 1091–1092
of small intestine, 825
soft tissue, 271–272
necrotising, 272b
staphylococcal, 299–301, 300f
cannula-related, 300, 300b
methicillin-resistant Staphylococcus
aureus, 300–301
skin, 300
staphylococcal toxic shock syndrome,
301, 301f
wound, 300, 300f
supportive therapy for, 966
transmission of, 98f, 108
tropical, 274–278, 275b
urinary tract, 599–602
antibiotic regimens for, 601b
investigation of, 600b
in old age, 600b
persistent or recurrent, 601, 601b
risk factors for, 600b
viral, 279–299
gastrointestinal, 292
with neurological involvement, 298–299
respiratory, 292–298
with rheumatological involvement, 299
sexually transmitted, 380–383
of skin, 290–292, 1091–1092
Infection-related glomerulonephritis,
573b–574b, 576
Infectious disease
genomics in, 55
pathogenesis of, 102, 105f
periods of infectivity in, 108b
principles of, 97
treatment of, 113–125, 116b
Infectious keratitis/corneal ulceration,
1228–1229, 1228b, 1229f
Infectious mononucleosis, 285–286
causes of, 285b
clinical features of, 285, 286f
investigations of, 285
management of, 286
Infective endocarditis, 462–465, 464b,
466b
acute, 464
antimicrobial treatment of, 466b
in old age, 463b
ophthalmic features of, 1219b
post-operative, 464
prevention of, 465
subacute, 464, 464b, 465f
Inferior petrosal sinus sampling, bilateral,
683f
Inferior vena cava, 388f, 560
Infertility, 671–672, 671b
cytotoxic medications and, 1291
in polycystic ovarian syndrome, 673
Infestations, skin, 1093–1094


INDEX • 1357

Viral hepatitis, 884–881. See also individual hepatitis viruses
acute clinical features of, 884–885 complications of, 885b causes of, 884b chronic, HIV-related, 360 features of, 885b immunisation, 885b investigations for, 885 management of, 885 pregnancy and, 1278 transmission, 885b treatment, 123b
Vitiligo, 131b, 1108, 1109f VDL. See very low-density lipoproteins Voiding. See Micturition Volatile substance, poisoning from, 231 Volume of distribution (V), 17, 18f
